*Signs.*—Scrofulous caries of the *knee-joint* may be taken as typical of the *general* symptoms. The disease approaches very insidiously, being preceded by little or no pain. Some inability to use the joint—a limping lameness in walking—first attracts notice. A child for example—the disease occurring commonly before puberty—drags his foot after him in walking. Weeks or perhaps months elapse ere pain is complained of; and then only a trifling pain, intermittent, but fixed, and aggravated by any movement of the joint, or especially on percussion of the bone below, and of the foot in disease of the knee-joint. This pain increases as the disease progresses. At length a swelling of peculiar character forms around the joint, arising from infiltration of the cellular texture with serum and lymph. A puffy, elastic swelling is thus produced, which assumes a *globular* shape, while the skin retains its white colour, constituting the “white swelling,” formerly recognised in Surgical works. This swelling becomes more conspicuous and apparently larger than it really is, owing to gradual wasting of the muscles above and below the diseased joint. Scrofulous enlargement of the knee-joint, for example, thus *differs* notably in its characters from the swelling of Synovitis. The absence of pain in the first instance, and for a considerable period, is also diagnostic. In either disease, the limb becomes somewhat flexed, from muscular action prevailing in that direction. The general health remains comparatively undisturbed up to this period.

*Course and Terminations.*—Scrofulous caries of a joint may sub-

side, leaving only some œdematous swelling and stiffness of the joint. Or, the disease progresses, both to the surface, and the interior of the joint.

In the one direction, as the disease advances, the periosteum becomes detached, *suppuration* takes place *around* the joint, and sinus-openings form, leading down to worm-eaten carious bone, and giving vent to a foul discharge. The textures are undermined and traversed by sinuses

FIG. 217.

in various tortuous ways, according to the anatomical relations of the joint. (Fig. 217.) Towards the *joint*, as caries extends, the nutrition of the cartilages, depending on the osteal vessels, becomes impaired. Their attachment to the bone is loosened, and they acquire a fibrous character. *Ulceration* commences, usually, on the deep or osseous surface of the cartilages; as a disintegration equivalent to the carious state of the bone. Portions of cartilage may be detached and lie loose within the joint. Sometimes, the ulceration assumes a peculiar form, which has been named "spotted ulceration;"

there being several pits containing a curdy matter in the articular surfaces, and which correspond to pits in the bone, while the intervening portions of cartilage remain unaltered.

Ulceration of the articular cartilage is announced by painful startings of the limb, occurring particularly at night. Synovitis speedily supervenes, and the formation of matter *within* the joint. The opposite articular cartilage becomes affected and the bone exposed. The two sensitive osseous surfaces meeting together and being subject to attrition and pressure by spasmodic action of the muscles, the starting pains are much aggravated. The ligaments share this destructive progress of the disease, and give way; the *abscess* within the joint bursts through the synovial membrane, and at length finds its way to the surface, with sinuous openings around the joint. The head of the bone, altered in size and shape, and no longer restrained by ligamentous connexions, undergoes *dislocation*; in whatever direction the disease may facilitate displacement, and subject to the action of the muscles.

The joint has thus become irreparably disorganized; but *ankylosis* may take place without dislocation, or an imperfect *joint* form after dislocation, the bone remaining in its new locality. Either of these reparative terminations, in the course of nature, are rare.

Constitutional disturbance of the most severe kind accompanies the destructive course of this disease; and the patient probably sinks ultimately from long-continued pain and sleeplessness, purulent discharge and the night sweats of hectic.

The concurrence of scrofulous disease in other organs, than the joints, must not be overlooked in our *prognosis*. Thus, the lungs or mesenteric glands may be affected with tubercular deposit; or tubercular meningitis ensue, with effusion into the ventricles of the brain. And

the social state of the individual should be taken into account; scrofulous disease arising and progressing far more readily in the poor and needy, than in the affluent classes of society.

*Treatment.*—Local appliances are of subordinate importance to constitutional treatment, yet they are co-operative in arresting scrofulous caries and the reparation of its destructive consequences.

In the first place, absolute *rest* of the limb is an essential condition throughout this disease; in the earliest stage to arrest its progress, subsequently to relieve pain and induce ankylosis. Due regard should also be had to the *position* most favourable for the future use of the limb, in the event of this issue. Such rest, and position, can only be secured by means of a suitable splint. A leather or gutta-percha splint moulded to the joint answers best, generally. But the splint must be of sufficient length to fix the limb entirely, and check any contraction of the muscles which would affect the joint. Thus, in scrofulous disease of the hip-joint, a gutta-percha splint should be applied so as to embrace one side of the pelvis and two-thirds of the circumference of the thigh, and extend from the short ribs to below the knee. The limb should be in a line with the trunk, or bent only *slightly* forwards. For the knee-joint, two lateral splints are preferable; supporting two-thirds of its circumference, and extending from the middle of the thigh to the middle of the leg. A *slightly* flexed position will be the most convenient in the event of ankylosis. For the ankle, also, two lateral splints may be made to include the lower part of the leg and the sole of the foot; the patient being allowed to walk about with the knee supported by a wooden leg. Disease of the bones of the foot, will require the support of a splint moulded to the sole, and turned round the inner and outer side. Over this, a large cloth boot may be worn, whereby the patient can walk about without injury to the diseased joints. In the upper extremity, scrofulous disease of the joints must be treated on a similar principle as to rest, and position. For the shoulder, a splint should be moulded to the joint, and extend down the arm to the elbow; the forearm being suspended in a sling from the neck. A diseased elbow-joint is best supported by lateral splints; the wrist by a splint on its palmar surface, extending upwards to near the elbow and downwards to the tips of the fingers, and doubled at its margins over the sides of the hand and forearm.

In an *advanced* stage of the disease, when painful startings of the limb, and a tendency to dislocation have supervened; it becomes advisable to slightly separate the diseased *articular* surfaces, and counteract muscular contraction. Some *extending* force, moderate but constant in its operation, may be advantageously resorted to. For the hip-joint, Liston's long splint, interrupted, will accomplish this purpose. The knee-joint is, perhaps, best managed by a pulley sling-apparatus which encloses the limb in a canvas-trough; while slight extension is maintained by the inclined direction of the pulleys. This apparatus—applicable also to fracture of the thigh or leg—gives great ease and comfort in advanced disease of the knee-joint. Other joints may be subjected to contrivances which seem most effectual.

Lastly, whatever be the *termination* of scrofulous caries, a *starched bandage* is an exceedingly useful support. If the disease be arrested, leaving only some oedematous swelling of the joint; the uniform pressure of this support will aid in reducing the swelling, and the patient

can get about on crutches—supposing the lower limb to be affected—with the benefit of air and exercise. If ankylosis have ensued, or a new joint as the result of dislocation; the support of a starched bandage will be equally advantageous. The period of time necessary for the use of some support to the seat of disease is always considerable; many months, possibly years.

Other local treatment—from first to last—may be regarded as comparatively unimportant. Scrofulous disease of a joint cannot be arrested by any depletory measures, and in proportion as they reduce the general health such measures are positively injurious. *Local blood-letting*, by a few leeches, may sometimes prove advantageous in the incipient or vascular stage of the disease. But the repeated loss of blood would be injurious. *Counter-irritation*, by blisters, setons, &c., has an equally restricted applicability. The discharge and pain they occasion, more than counterbalance any good resulting from their *derivative* action, especially in children. If the disease subsides, with œdematous swelling; *stimulating* applications have some beneficial influence. Hence, embrocations, iodine paint, and douches of sea-water, are now useful. Pressure also—as by a starched bandage, or pressure with stimulation—by Scott's strapping, may be applied with advantage.

*Abscess* having formed—as the disease progresses; a free and dependent opening should be made in time to prevent burrowing of the matter. The starched bandage can still be used, with a trap-opening opposite the abscess, for the convenience of dressing and cleanliness.

The local treatment of scrofulous caries of a joint, thus generally resembles that of synovitis; in respect to rest and position of the joint, topical applications, and the treatment of abscess. But the *constitutional* treatment of this disease is precisely that of Scrofula. This treatment consists in a course of tonics, especially the preparations of iron and quinine, a nutritious diet, including cod-liver oil, pure air, daily exercise, and sea-bathing. The administration of medicinal tonics should be varied from time to time, and with occasional intermissions. For children, the *vinum ferri* seems preferable, and after a while the syrup of the iodide of iron may be given in exchange; these and other simple preparations of iron being continued for three or four weeks, and then omitted for a week or ten days. But this course of treatment must be extended over a considerable period, probably two or three years.

ULCERATION OF ARTICULAR CARTILAGES.—*Structural condition*.—The articular cartilages, when fully developed, and in a healthy state, are destitute of blood-vessels (and nerves). Nutrition is effected—as in the cornea—by imbibition; the nutrient matter being drawn from the blood-vessels of the subjacent bone and vascular fringe of the synovial membrane around the circumference of the cartilage. As the result of inflammation—according to the observations of Sir B. Brodie, Mayo, and Liston—blood-vessels extend into the cartilages from the subjacent bone; just as they form in extravasated lymph. Hence the nutrition of articular cartilages, in this state, depends on a supply of nutritive matter, directly from the vessels, as in other vascular textures. But this question of the *vascularity* or *non-vascularity* of cartilage—with regard to the more or less direct supply of blood, has nothing whatever to do with the nutritive process itself as pertaining to the elemental structures, in health and disease. In regard to ulceration of the articular cartilages, the researches of Goodsir and Redfern, more particularly, have shown, that it represents

a vital alteration in the cartilaginous structure itself; and that the influence of the neighbouring blood-vessels is only indirect or secondary.

As consequent on inflammation of the *synovial membrane*—synovitis, or of *bone*—ostitis, ulceration of articular cartilage may be named *inflammatory* ulceration, or *secondary*, in its relation to the original disease. Similar ulceration may also occur as an original disease of the cartilage, and is hence named *primary* ulceration. But this state would seem to be, usually, a degeneration. Degeneration precedes inflammatory ulceration when the disease originates in *bone*, and extends to the cartilage as a secondary affection.

Ulceration may *begin*, either on the *free surface* of articular cartilage, or on its *attached surface*; and at its *margin*, where the synovial membrane is reflected over it, or in the *substance* of the cartilage. In the hip, it may commence close to the attachment of the round ligament; or in the knee, adjoining the crucial ligaments.

Forming shallow excavations, these assume the appearance of grooves, at a greater or less distance from the margin and frequently in the central parts of the cartilage. Nearly the whole cartilage may disappear, leaving only a few isolated reddened patches.

Inflammatory ulceration—consequent on *synovitis*, presents the following alterations, on the free surface of the cartilage. The colour of the cartilage is altered in spots; which either rapidly become holes, as if cut out with a chisel, or the spots assume a fibrous aspect, and becoming excavated, form pits with fringed margins. Thus, the cartilage may be extensively destroyed, and the bone laid bare. Or, and especially in serofulous synovitis, a thick vascular membrane forms, which passes from the diseased synovial membrane over the cartilage. The cartilage—as Mr. Barwell describes it—slowly undergoes transformation into a kind of granulation, between which and a similar material growing from the synovial membrane, adhesions ensue, resulting in absolute continuity. When ulceration of the cartilage has extended deeply, the bone becomes involved, and the cancellous tissue acquires undue vascularity. The articular lamella of bone—a layer of calcified cartilage—crumbles or breaks up in masses, carrying with it portions of cartilage; and the granulations springing from the exposed cancellous tissue unite with those of the synovial membrane.

Ulceration consequent on disease of the *subjacent bone*, consists—according to Mr. Barwell—in degeneration, followed usually by inflammatory ulceration. A portion of the cartilage, losing its nutrient supply, degenerates or perishes, and is detached with its articular lamella from the inflamed surface of bone; whilst the surrounding portions of cartilage undergo the changes described as occurring in ulceration from synovitis.

The *minute* changes in this process of ulceration relate both to the cartilage-corpuscles and the inter-cellular or hyaline substance. The corpuscles enlarge, with an endogenous development of cell-structures, and bursting, discharge their contents into cavities in the tissue itself, or upon the free surface, mingling with the organic matters contained within the joint, and probably forming pus. This endogenous productiveness is greater, the nearer to the seat or focus of disease. There, instead of two or three nucleated cells, the corpuscles may contain an almost indefinite number of younger cells, resembling pus-globules. The inter-cellular or hyaline substance undergoes disintegration, or in more chronic ulceration, it becomes split into bands or fibres of varying size, in the midst of

which, sometimes, are found gelatinous masses; the changed contents of the cartilage corpuscles as Dr. Redfern supposes.

These changes occur more or less rapidly in proportion to the activity of the disease; thus representing the *acute* and *chronic* varieties of ulceration. In one case, the patient having died after venesection, Mr. Lawrence believed that complete destruction of the articular cartilages of the femur and tibia took place in four days. Chronic ulceration may progress very slowly, especially when of rheumatic origin.

*Signs and Diagnosis.*—(1) *Secondary* ulceration of the articular cartilages is announced by the *starting pains* adverted to in connexion with the *progress* of synovitis and scrofulous caries; and the articular disease is preceded by the symptoms of one or other of these diseases. (2) *Primary* ulceration, of an inflammatory character, presents certain special and distinctive signs, as compared with synovitis or caries. *Pain*, fixed and intense, is the earliest symptom, and coincident with the *commencement* of the disease. This pain is aggravated by movement of the joint or friction—rather than by percussion of the bones—and accompanied with startings of the limb, as muscular spasms supervene. In the course of weeks or months, slight *swelling* arises, corresponding in shape to the margin of the affected cartilages, and produced by serous effusion into the cellular texture externally. Abscess, within the joint, follows.

*Repair*—after ulceration of articular cartilage—takes place in different ways. Extensive destruction of the opposed cartilages, with exposure of the cancellous bone; may be followed by the formation of granulation-tissue, uniting the osseous surfaces, and resulting in ankylosis. Ulceration affecting the cartilage to a considerable depth is sometimes repaired—as Redfern describes—by the formation of a fibro-nucleated membrane from the substance of the cartilage, without the occurrence of any new exudation. Occasionally, a patch of ivory-deposit or porcelainous-encrustation, occupies the place of a portion of cartilage; or a scar alone marks the seat of a former ulcer.

*Treatment.*—The *local* treatment is the same as for other inflammatory diseases of the joints. Absolute rest, and position of the joint, must be observed, and for a considerable period. Counter-irritation, by blisters, issues, or caustic potash, may be applied more advantageously than in scrofulous caries. Abscess must be opened forthwith, and ankylosis induced, as the only favourable termination in this advanced state of the disease. Excision or amputation are ulterior resources, which will be considered with reference to Diseases of the Joints, specially. (Chapter XXXVII.) The *constitutional* treatment resembles that for rheumatism affecting the joints. Mercury, in the form of calomel, the bichloride, or blue-pill, combined with opium, should be administered, and pushed to slight salivation. Mercurial inunction must be resorted to, if the internal administration disagree. This may be followed by iodide of potassium and sarsaparilla. But subsidence of the joint-symptoms will soon declare whether the articulation itself is preserved, or ankylosis be inevitable.

*ANCHYLOSIS, OR STIFF JOINT.*—*Structural Conditions.*—Two states of ankylosis are recognised; the *fibrous* or incomplete; and the *osseous* or complete. Both signify the junction or union of the *articular* surfaces of the *bones*, thus presupposing the partial or complete removal of the articular cartilages; unless occasionally, in fibrous ankylosis, where bands of false membrane may be thrown across the synovial capsule, forming adhesions, with some stiffness of the joint. Either condition of

anhylosis may be *extracapsular*; the fibrous consisting of a thickened and indurated state of the ligamentous capsule, with adhesions around the joint; and osseous anhylosis externally, being the formation of new bone around the joint.

(1) *Fibrous anhylosis* is liable to happen to any joint; and the shortened and contracted state of the muscles acting on the joint gives an apparent firmness to the anhylosis, beyond that due to the joint-condition.

(2) *Osseous anhylosis* occurs most commonly in the hip, knee (Fig. 218), or elbow; the articular surfaces seeming to be fused together, as seen more clearly on a vertical section of the bones.

Both states of anhylosis are attended with a proportionate loss of mobility in the joint; the fibrous allows of some degree of motion, more so, perhaps, under chloroform; the osseous presents a perfectly rigid and immovable joint.

Both anhyloses are also accompanied with more or less *deformity* of the *limb*, arising from mal-position of the bones obediently to muscular contraction; unless the anhylosis has resulted under proper and effectual surgical supervision.

The *Causes* of anhylosis have reference to inflammatory diseases of the joints; synovitis, caries, and primary ulceration of the articular cartilages, as already described. Destruction of the cartilages thence ensuing, may be succeeded by *reparation*, in the form of anhylosis. The fibrous state represents the incomplete result of reparation; the osseous state, its completion, by the transformation of the fibrous matrix into bone.

*Treatment*.—*Preventive* measures consist in the prompt and efficient treatment of the diseases leading to anhylosis; while the precaution should also be taken of securing the limb in such *position* as shall be most useful in the event of this result.

*Remedial* treatment consists, in restoring, if possible, the mobility of the joint, and correcting any deformity of the limb. Or the latter may be the main object in view.

*Fibrous anhylosis*—admitting of some motion in the joint—commonly yields to passive motion, from time to time; thus gradually regaining the use of the joint. Firmer union will, probably, have to be overcome by forcible *flexion* and *extension*, under the influence of chloroform. The joint yields with a creaking cleavage and successive snaps, which are both heard and felt. Any resisting tendons may be divided subcutaneously, tenotomy completing the cure. The knee or elbow-joints, for example, can thus be restored to a fair degree of mobility, and the limb brought to a good position. When these manipulative or operative procedures have failed; if then the fibrous anhylosis be incompatible with a good use of

FIG. 218.\*

\* Bony Ankylosis of Knee-joint, with extreme mal-position—tibia forward at right angle with femur. (A. Cooper.)

the limb, as in the case of such ankylosis of the knee-joint; *excision* of the joint may advantageously be resorted to; and the more so, in proportion to *mal-position* of the limb.

*Osseous ankylosis* cannot be overcome by any justifiable force of extension. If, therefore, the limb be comparatively useless, as in the case of the elbow-joint, *excision* must be had recourse to. The removal of a wedge-shaped portion of bone above or below in connexion with the ankylosed joint, may be necessary to correct an angular deformity of the limb in the case of the knee-joint. In any case of osseous ankylosis, the propriety of excision will also depend on the *mal-position* of the limb which may accompany the ankylosis. *Amputation* will be warrantable only in the extreme case of a useless limb, and which cannot be made tolerably serviceable by excision.

**LOOSE CARTILAGES IN JOINTS.**—Small moveable bodies occasionally form within a joint, and which may be quite free, or attached by narrow peduncles to the walls of the articular cavity. One such body sometimes exists, but not uncommonly two or three, and possibly, many. In the left knee of a woman who died of apoplexy, Morgagni found twenty-five smooth and polished globular bodies. Varying in size from a barley-corn to a chestnut, they are roundish or flattened, elongated or tuberos. In consistence, colour and structure, these bodies may be soft and of a yellowish colour, like little masses of fibrine; or hard, whitish and glistening, consisting of cartilage or fibro-cartilage; or converted into bone. Neither the term "cartilage" nor "loose," is, therefore, universally applicable.

Any joint possibly, may be the seat of these bodies; but they occur usually in the knee, and less frequently in the elbow, shoulder, or lower jaw.

They seem to *arise* from the vascular processes of the synovial membrane, as out-growths of that membrane, projecting into the joint. They remain connected, or become detached, and are liable to undergo the changes of appearance and structure, above described. These cartilaginous bodies form most frequently as the result of chronic rheumatic synovitis; and more often in adults than at an earlier period of life. Other modes of origin seem probable in some cases. Thus, the fibrinous concretions may, perhaps, represent exudations, or precipitations from the synovia. Portions of bone becoming detached from the articular surfaces, or resulting from ossific deposit, give rise to similar symptoms.

**Symptoms.**—It will be readily supposed that any such foreign body getting nipped in between the articular surfaces, must occasion some remarkable symptoms. Hence, an attached cartilaginous body may remain quiescent; a detached, or entirely loose cartilage, moving about in the synovial capsule, is more apt to slip in between the bones. Up to this time the patient may have experienced occasional twinges, as if of rheumatic character; but now a sudden, intense, and sickening pain seizes him; and the joint becoming instantly locked, the hitching or fixed inability to move the limb, may throw him to the ground in the act of progression. Sudden dislodgment of the intervening cartilage is equally apt to occur, whereby the joint is immediately restored to its original state of painless mobility; leaving only perhaps a little temporary effusion. These symptoms having recurred at intervals, on the slightest movement, and sometimes during sleep; the sufferer seeks relief. On careful examination, a foreign body can usually be found, and by palpation brought

perhaps to a stand-still at the edge of the patella—in the knee-joint, and there made to bulge under the skin; but the little smooth cartilage easily slips away from under the finger and again disappears.

Ultimately, the joint itself sometimes becomes diseased; prolonged irritation inducing synovitis with relaxation of the ligaments, which are loosened also by having been stretched by the repeated interposition of the cartilage between the articular surfaces.

*Treatment.*—Recurrence of the attacks of pain may be prevented by limiting the motions of the joint; thus fixing the loose cartilage, temporarily, or perchance permanently. Hence, an elastic bandage or knee-cap should be constantly worn. Often the relief afforded is such that no further interference becomes requisite.

*Removal* of the foreign body, is the only other resource; but this should never be lightly entertained, considering the risk to the joint and even to life, contingent on the operation of extraction. It is justifiable only when the cartilaginous body is loose, and freely moveable, of some size, and apparently single. Taking a favourable opportunity—after the pain and irritation of an attack have subsided—this operation may be performed, in either of three ways. It is more difficult than would appear to one who has not done it. The cartilage must first be carefully fixed, in a steady spot, with the forefinger and thumb. In the knee, it may be made to project on one side of the patella. The skin is then to be drawn to one side, and an incision made *directly* down upon the cartilage, which is thence allowed to *escape*. On relaxing the skin, the valvular aperture is at once closed with a strip of plaster, and the limb should be kept at rest until any symptoms of synovitis have subsided.

Another mode of operation, consists in introducing a tenotomy knife *slantingly* underneath the skin and dividing the synovial capsule upon the fixed cartilaginous body; then squeezing it through the synovial aperture into the external cellular texture, where it is allowed to *remain*, the integumental aperture is closed with a strip of plaster. If the cartilage should not become absorbed, it is extracted from its bed by a *subcutaneous* incision, when the synovial aperture has healed, after the lapse of some days.

Both these methods of operation are hazardous; but the subcutaneous one is less so than the immediate mode of extraction, as would appear from a large number of cases the results of which were compared by M. Larrey. In 167 cases of removal of loose cartilages by operation; 121 were cases of the direct operation, and 98 were successful, 5 doubtful, and 28 died; whilst of 39 subcutaneous operations, 19 were successful, 15 failed, and 5 died.

A modification of the subcutaneous operation has been practised by Mr. Square of Plymouth; and by which Mr. Erichsen states that he has successfully removed in succession five loose cartilages from one knee. The capsule having been divided subcutaneously over the fixed cartilage, it is pressed *into*—not through—the synovial aperture, and retained there by a compress and strips of plaster. Adhesion speedily ensues, followed by absorption of the cartilage.

Mr. Syme recommends yet another method, by which, he says, he generally succeeds without risk. It consists in “making a free subcutaneous incision through the synovial membrane and cartilage, and applying a blister over the part where it is retained.”

TUMOURS CONNECTED WITH JOINTS.—*Cancer* of the *Articular* ends of

Bone is sufficiently described in connexion with Cancer of Bone generally. "In *cartilage*" observes Virchow in his Cellular Pathology, "malignant affections are so rare, that it is usually assumed to be altogether insusceptible of them." The *synovial membranes* are equally indisposed to cancerous disease. Sir B. Brodie states, that he had "no reason to believe that any truly malignant disease ever has its origin in the synovial membrane."

For other Morbid Growths in the articular ends of Bone—see TUMOURS OF BONE.

NEURALGIA OF JOINTS is specially important in relation to the *diagnosis* from structural disease—see affections of the NERVES.

## CHAPTER XXXV.

### DISEASES OF PARTICULAR JOINTS.

DISEASES OF THE HIP-JOINT.—The hip-joint is liable to the same inflammatory diseases as other joints, affecting its component structures; synovitis, scrofulous caries, and ulceration of the articular cartilages. The second-named disease presents characters worthy of a separate description.

SCROFULOUS DISEASE OF THE HIP, OR MORBUS COXARIUS.—*Structural condition*.—This disease commences in the *cancellous tissue* of the head of the *femur*, or of the *acetabulum*; possibly, in both bones simultaneously. It may also commence in the synovial membrane, as scrofulous synovitis; or, it is said, in the round ligament. Hence, the name, *scrofulous disease* of the hip, as a general term including these different *seats of origin*.

In scrofulous caries of the hip, the cancellous tissue undergoes the structural alterations described in connexion with this disease of Bone; briefly, increased vascularity, softening, deposition of a reddish fluid in the enlarged cancelli, followed by a yellowish opake tubercular matter.

*Subsequent structural alterations* are as follow:—The *articular cartilages* become involved and disappear, more or less completely; and abscess forms within the cavity of the joint. The affected portions of bone become remarkably changed in shape and size. The *head* of the femur—bared perhaps of cartilage and the open cancellous tissue exposed—is flattened and expanded, mushroom like in form on the neck of the bone; and the *neck* itself sharing in the disease, may be so reduced, as to leave nothing more than a slight nodular vestige, if any remnant, of the diseased bone projecting from the great trochanter. This portion of the bone, and the adjoining portion of the shaft, are not unfrequently carious; either by an extension of the joint disease, or as the original seat of caries. The *acetabular cavity*, also denuded of cartilage, is enlarged in circumference, but shallow; the cotyloid ligament and bony rim of this cavity having been destroyed. The *round ligament* may have disappeared, and the *capsular ligament* at length giving way, the abscess bursts into the surrounding cellular texture. Thus the joint is utterly destroyed.

*Terminations*.—(1) *Anchylosis* rarely takes place, as a mode of repairation. (2) The remnant of the articular end of the femur is drawn up

by the action of the muscles into the patulous acetabulum. Thence the femur has even been forced through the thinned carious bottom of this cavity, and *entered the pelvis*. (3) But the ill-fitting, loose, articulation from advanced disease, is mostly liable to *dislocation*. The femur drawn upwards and outwards by the glutei muscles, passes over the reduced brim of the acetabular cavity, and slipping on to the *dorsum ilii*, lodges there. More rarely, the femur is thrust out of the acetabulum forwards, and rests on the *ramus* of the *pubes*. *Abscess* finds its way to the surface by burrowing sinuous tracks, and opens in various situations. The openings relate somewhat to the seat of the disease. When it originates in the head of the femur, the sinus extends some way down the thigh, and opens probably near the insertion of the tensor *vaginæ femoris* muscle. Acetabular disease presents a sinus-opening in the gluteal region near the anterior inferior spine of the ilium. Matter may also pass down by the rectum, bursting into it, or close to the anus. If the pelvic bones be involved, a sinus opening is presented in the pubic region, above or below Poupart's ligament; above the ligament, it leads probably to intra-pelvic abscess; below the ligament, to disease of the *rami* of the pubis or ischium.

*Signs*.—(1) Scrofulous disease of the hip-joint approaches, and progresses, very insidiously. Commencing generally in early life, under the age of puberty, scarcely any pain is complained of in the first instance, or for weeks, possibly months, as the disease slowly progresses. The first perceptible sign is a *slight limp* in walking; the child shuffling, hobbling, or dragging his leg, step by step. When standing still, the whole weight of the body is thrown on the other limb, to relieve the halting member. This *attitude* is peculiar; the hip of the sound limb being elevated, gives an obliquity to the pelvis downwards on the diseased side; the thigh is slightly bent on the pelvis, and the leg on the thigh, the toes touching the ground. The limb may be somewhat abducted and everted, the toes being turned outwards; in this particular resembling dislocation on the pubes, or fracture of the neck of the femur. But, in the *first stage* of diseased hip-joint, the limb is *apparently elongated*. This, however, is a *déceptive appearance*, arising from the obliquity of the pelvis downwards towards the diseased hip; measurement with a tape from the anterior superior spine of the ilium to another fixed point below the joint, the inner malleolus, will at once show that there is no elongation in reality. The limb becomes *wasted*, from disease, the gluteal muscles especially; so that the buttock is flattened and flaccid, wider than natural, and the lower fold of the nates less marked. *Pain* is now felt in the hip, or referred more to the inner side of the knee; and the pain in the former situation is aggravated by any attempt to bear on the joint, by abduction, or rotation of the limb, and especially by concussion of the bones, as by striking the trochanter or jerking the limb upwards from the sole of the foot. Pain on the inner aspect of the knee is a sympathetic sensation; depending, probably, on the nervous relation between the hip and knee, through the obturator and perhaps the anterior crural nerves. Both these nerves supply articular branches to the hip, and to the inner side of the knee.

(2) *Real shortening* of the limb—succeeding its apparent lengthening—marks the *second stage*, as it has been termed, of this disease. It coincides with advancement of the disease to *destruction* of the *cartilages* and of the head of the femur, acetabulum, or both bones; whereupon

the limb is drawn up by muscular action. Shortening varies, therefore, in different cases, but it increases as the disease progresses. The *attitude* of the limb is somewhat changed; still remaining flexed, it has now also become *inverted*; in this particular resembling dislocation backwards on the dorsum ilii or into the ischiatic notch. Lateral inclination of the pelvis has, at length, produced a compensatory *lateral curvature of the spine*. Wasting of the limb increases. This shortened, flexed, inverted, and wasted limb; with obliquity of the pelvis and twist of the spine; present a very characteristic appearance. Pain also has become more severe, and aggravated by the attrition of the exposed surfaces of bone, subject to spasmodic muscular action, has acquired the character of *starting pains*.

*Abscess* within the joint bursts into the surrounding cellular texture, and forms a swelling in connexion with the hip; which up to this time had undergone no further alteration than a slight fulness in the groin, and enlargement of the inguinal glands. Abscess-swelling is rendered more conspicuous by the wasting of the thigh and buttock. When, at length, the abscess opens externally, the situation of the *sinus apertures* denotes, as already indicated, the probable seat of the disease; whether in the head of the femur or acetabulum. *Dislocation* is very apt to supervene; commonly on the dorsum ilii; yet, although attended with increased shortening, the attitude of the limb, flexed and inverted, remains the same. But the head of the femur or its remnant, with the great trochanter, can be felt in its new situation, on the back of the ilium; and often very distinctly, the gluteal muscles having wasted so much that the bone seems to lie immediately under the skin. The additional symptoms—wasting of the limb, and sinuses discharging an unhealthy pus and leading down to diseased bone, complete the local diagnostic differences of appearance from *traumatic* dislocation. The general health also has now become worn down by irritation and hectic; and this constitutional condition, coupled with that of the diseased limb, form a picture which leaves little or no doubt as to the nature of the case, not to mention the previous history of its insidious origin.

*Diagnosis*.—Scrofulous disease of the hip-joint is liable to be mistaken for other diseases, if *any one* particular symptom be alone considered. It may resemble rheumatism, disease of the knee, lateral curvature of the spine, infantile paralysis with wasting and defective growth of the limb, psoas abscess, abscess near the joint, inflammation of the bursa under the psoas-iliac muscle, and congenital dislocation of the hip-joint. But the concurrence of symptoms, and as compared with those of each of these diseases, will determine the diagnosis.

*Treatment*.—The directions given with reference to scrofulous disease of the joints generally, are here applicable; rendering any repetition of detail unnecessary. Absolute rest of the joint must be secured, and a position favourable to the future use of the limb, in the event of ankylosis. A splint moulded to the hip and extending below the knee, with the limb straightened, will best answer this twofold purpose. Subsequently, the long straight *extending* splint may be applied with more advantage; thus to counteract muscular spasm and pain coincident with ulceration of the cartilages in contact, and the liability to dislocation as the disease advances. The accompanying extending apparatus is said to answer admirably; but I have had no experience of its use. (Fig. 219.) It is a combination of the leathern hip-splint advocated by Sir B. Brodie,

with Dr. Davis's metallic lever; but the simple manner in which it is made to control any rotative or abducting movement of the limb, is peculiar.

FIG. 219.

FIG. 220.

*Contraction of the hip, taking place subsequently, may be counteracted by the annexed apparatus (Fig. 220), which successfully combats each abnormal mal-position of the limb. The pelvic band bears two lateral uprights, upon which the armpits rest, and from which strong laced bands pass around the thorax. This instrument is especially adapted for cases of severe hip-contraction.*

Abscess should be opened to prevent burrowing of the matter among the muscles. The situation of pointing is selected, usually about an inch above and behind the great trochanter. For the convenience of dressing, a long "interrupted" splint may be used. The general treatment, medicinal and hygienic, consists, in a course of iron, quinine, cod-liver oil, and nutritious diet, with as much pure air as possible. I have very beneficially placed my hospital patients in bed in the quadrangle of the hospital, for some hours daily, weather permitting.

This plan of treatment must be pursued for a considerable period—some weeks or months—to solicit ankylosis; or the subsidence of the disease, possibly, after dislocation, and a free discharge of matter with the detritus of the carious bone.

Failing thus to bring the disease to a termination, and the general health declining, operative interference becomes imperative. This will be considered under *Excision of the Hip*.

CHRONIC RHEUMATIC SYNOVITIS OR ARTHRITIS—MORBUS COXÆ SENILIS.  
 —*Structural Condition.*—This disease contrasts with scrofulous disease of the hip-joint, principally in the formation of osseous depositions or outgrowths around the joint, and in the absence of suppuration.

*Signs, and Diagnosis.*—The former structural difference gives to the neck of the bone an enlarged and irregular character; which, however, can scarcely be detected, as a sign, at the bedside. But the *dry* character of this disease,—the absence of suppuration in the joint, and its consequences,—the swelling of abscess and the discharging sinuses which ensue, are perceptibly distinctive. Shortening of the limb to some extent occurs, as the disease advances to destruction of the articular cartilages, with expansion of the head of the bone, and lowering of its neck to even below the level of the great trochanter.

The disease progresses slowly, and is thus clearly distinguished from the sudden result of fracture. Other articulations being or becoming affected, would leave no doubt as to the nature of this condition. The general health is often little disturbed, the disease appearing as a local affection. It seldom occurs under the age of forty; differing in this respect from scrofulous disease of the joint, as well as in its pathology and consequent symptoms.

*Treatment*—see Chronic Rheumatic Synovitis.

NEURALGIA of the Hip.—The *diagnostic* Symptoms of Neuralgia are pointed out in connexion with affections of the NERVES.

Neuralgia of some duration is attended with the alterations of attitude consequent on disease of the joint—whether scrofulous or rheumatic. The weight of the body being habitually thrown on the sound limb to relieve the affected joint of the other side, the limb on *this* side becomes apparently lengthened and flexed, the toes touching the ground; the pelvis is inclined obliquely to the same side, and some compensatory lateral curvature of the lumbar spine results. But, with neuralgia, no real *shortening* of the limb ever ensues.

DISEASE OF THE SACRO-ILIAC JOINT.—*Structural Condition.*—The cartilaginous lamella of the sacro-iliac articulation seems to be the seat of a disease, occasionally affecting this joint. Ulceration of the cartilage, as the primary change, involves the synovial membrane; both of which structures are thus destroyed more or less completely. But, the ligaments remain unaffected, or are only partially destroyed; and the adjoining osseous surfaces do not become carious or necrosed. This disease is of very rare occurrence. It is, however, particularly noticed by Nélaton and Erichsen.

*Signs, and Diagnosis.*—*Pain* is one of the earliest symptoms. It is confined to the region of the joint, and increased by any movement or position whereby the weight of the body is thrown upon the sacro-iliac joint. Thus, walking, stooping, or even standing, is attended with a sense of painful weakness in that situation, and as if the body were falling asunder. When the pelvis is at rest, the *hip* may be moved in any direction without pain. It acquires a gnawing or rheumatic character as the disease advances. Inability to support the weight of the body, occasions an insecure, *wriggling gait*, from side to side; thus differing from the dragging lameness of the limb in disease of the hip-joint. *Swelling* makes its appearance over the joint; it is pulpy and elastic, and of an elongated shape in the line of the articulation. The limb is *apparently elongated*, owing to a drooping of the pelvis on the diseased side, the limb being

disused to support the trunk ; and this side of the pelvis is tilted forwards. Consequently, the anterior superior spine of the ilium, is both on a lower level and more prominent forwards, than on the sound side. Measurement, however, from that prominence to the inner malleolus shows that the limb is not elongated,—that any apparent lengthening—say half an inch, is not due to any change in the three large joints, or in the bones of the limb ; but that it must depend on some alteration above the anterior superior spine. Usually, the limb is *straight*, and becomes *wasted* as the disease progresses.

*Abscess* occurs at a late period. It forms over the diseased articulation, but spreads in various directions. The matter may point posteriorly near the articulation, passing upwards perhaps to the loin, upon and just above the crest of the ilium, there forming a fluctuating swelling of considerable size ; or extending outwards over the buttock, it reaches forwards nearly to the trochanter, as a great gluteal abscess. In both these situations, lumbar and gluteal, the abscess is *extra-pelvic*. *Intra-pelvic* abscess, the matter accumulating within the pelvis, may pass out of the sciatic notch, and thence under the gluteal muscles ; or gravitate downwards into the ischio-rectal fossa, and present by the side of the rectum, or vagina ; or open into the rectum and discharge per anum. *Shortening* of the limb takes place, in consequence of, and proportionate to, the destruction of the sacro-iliac articulation. In one case, related by Sir B. Brodie, the ilium seemed displaced and drawn upwards, so as to shorten the affected limb by two inches.

The *diagnosis* will have to be made—as Mr. Erichsen observes—between this disease, and that of the hip, disease of the pelvic bones, spinal disease, neuralgia of the hip, and sciatica.

*Causes*.—Acute inflammation of this articulation may result directly from *injury* ; as in a case given by Louis, a sack of corn having fallen on the loins of a man who was stooping at the time. In Sir B. Brodie's case, the symptoms seemed referable to pregnancy, four years previously. The disease has a scrofulous origin—according to Mr. Erichsen's experience ; but he has never seen it in young children, only in young adults from fourteen to thirty years old.

I have met with one case only, of this disease, of which the history, by my notes, was briefly as follows. F. H. H., aged eight, a weakly child from birth. The mother states that her four other children all died of water on the brain. Five years ago, this child fell down a long flight of stairs. Four months subsequently, she limped from side to side, in walking, like the motion of a milk-girl in carrying her pails. Shortly afterwards, she had intermittent fever, which lasted about two months. She met with a second fall down a flight of ten steps, and afterwards the limping gait became more marked. Then, the right gluteal region was observed, by her mother, to be larger than on the left side. For two years she continued to walk on crutches. During this period, some slight curvature of the spine had taken place, in the loins, and a spine-support was put on by a surgeon at the Orthopaedic Hospital, in Oxford Street. A swelling presented near the vagina, on the right side, and that in the gluteal region remained. In April, 1866, she was admitted to the Royal Free Hospital. The symptoms were those of the disease in an advanced stage ; abscess occupied the whole of the buttock, and pointed near the vagina ; thus being both extra-pelvic and intra-pelvic. Shortening of the limb, to a slight extent, had occurred, above the anterior superior spine of the ilium.

The *Course* of this disease, as already indicated, is most unfavourable; and thence the prognosis, is equally so. Continuing for months or years, the *termination* is nearly always fatal. In Sir B. Brodie's case, however, although shortening had occurred, recovery ensued.

*Treatment*.—The same treatment, local and constitutional, as for disease of the hip-joint, represents the little that can be done in disease of the sacro-iliac articulation.

Removal of the diseased articular surfaces, by excision, is, of course, out of the question.

## CHAPTER XXXVI.

### DEFORMITIES.

THIS large branch of Surgery forms the subject of several special Treatises. An abstract only—so far as the present discordant opinions respecting much of the pathology and treatment of Deformities, will allow—can be given here; sufficient for the requirements of the general Student, and for reference, in accordance with the design of this work.

Deformities may be arranged in two general classes:—1, Acquired Deformities; 2, Congenital Deformities or Malformations.

Class 1, embraces those deformities pertaining, in origin or result, to:—

- (1) The Integuments—Burn-cicatrices.
- (2) Bones—Fracture-union deformity.  
Rachitis, and Mollities Ossium.
- (3) Joints—Dislocations unreduced.  
Diseases of joints with Anchylosis, and  
Mal-position of the Limb.
- (4) Musculo-Nervous System.  
Spinal Curvature—Lateral.  
Deformities of Face and Neck—Wry-Neck—Squint.  
Deformities of Arm and Hand—Contractions.  
Deformities of Leg and Foot—Relaxations and Contractions—  
Knock-knee—Bow-leg—Club-foot.

The first three of these sub-classes are considered in connexion with other Injuries and Diseases; Deformities as Malformations also are thus associated;—*e.g.*, with Congenital Dislocations, and, with the pathology of Organs and Regions—Hare-lip, extroversion of the Bladder, &c.

It remains only to here notice the affections included in the last sub-class (4); associating therewith any remaining Malformations of musculo-nervous origin or character, as that of congenital club-foot. Even in this sub-class, the following Deformity is more conveniently considered elsewhere.

LATERAL CURVATURE OF THE SPINE.—See SPINE.

DEFORMITIES OF FACE AND NECK.—*Wry-Neck* or *Torticollis*.—This deformity is a twist of the head and neck to one side, in the directions of action of the sterno-mastoid muscle; the head being drawn downwards, sideways, and rotated somewhat outwards. The ear of the affected side may be

drawn down, so as almost to touch the clavicle. Sometimes the face is turned askew, the features losing their symmetry. The sterno-mastoid muscle is firm, and stands out more prominently, though shortened, as compared with that on the opposite side. Other muscles apparently become involved, the anterior margin of the trapezius acquiring an outline which defines the posterior boundary of that named triangular space of the side of the neck. The cervical vertebræ slowly undergo lateral curvature; but probably this symptomatic result occurs mostly in wry-neck connected with disease of those vertebræ.

*Causes.*—*Spasmodic contraction* of the sterno-mastoid muscle of the affected side, is the most frequent cause of *spasmodic wry-neck*. The special accessory nerve would seem to be the source of this muscular action, and hence its extension to the trapezius muscle. The spasm is remarkably jerking, painful, and constant, excepting during broken sleep, and it continues for many years; the sufferer ultimately sinking exhausted. This kind of wry-neck usually commences about the age of thirty, and in females, not apparently hysterical, but whose families have an hereditary tendency to other cerebro-spinal affections. *Paralysis* of one sterno-mastoid is a rare cause of *paralytic wry-neck*. The head is drawn to the opposite side by the healthy muscle, not being counteracted by its antagonist. *Disease of the cervical vertebræ*, of scrofulous or rheumatic character, occasionally gives rise to the deformity. The *exciting* cause would appear to be, not unfrequently, exposure to cold, or some occasion of local irritation or inflammation of the cervical glands, resulting in stiffness of the neck. Burns of the neck, followed by contraction of the cicatrix, occasion remarkable distortions resembling wry-neck; but not depending on any affection of the muscles, they are thus distinguished from wry-neck thence arising. *Congenital wry-neck* is said to be the most common form of this affection. The side of the head, neck, and shoulder which present the deformity, are considerably smaller than the parts on the opposite side; the shoulder and scapula are unduly raised, and the features drawn down and unsymmetrical. The sterno-mastoid muscle is reduced to a narrow, shortened cord, hard and tense. Curvature of the cervical spine has taken place, laterally to the opposite side, and a compensating curve in the opposite direction lower down.

*Treatment.*—Tenotomy or the subcutaneous division of tendons, and muscles, represents a principle of treatment, applicable to a large class of conditions; for the cure or correction of deformities depending on muscular contractions. Stromeyer introduced this principle, in 1831; and he was followed by other surgeons, who have established its remedial efficacy in various branches of Surgical Practice.

*Division of the sterno-mastoid muscle, subcutaneously.*—This procedure affords more or less complete relief of tension, when wry-neck deformity depends on contraction of the sterno-mastoid muscle. Thus, in spasmodic wry-neck, tenotomy is most successful, and in congenital wry-neck, less so; while in the paralytic form, and that arising from disease of the cervical vertebræ, this operation will be unnecessary or useless. The muscle should be divided close above the clavicle, the situation of least risk to subjacent parts. By introducing a narrow-bladed tenotome just above the sternum, the sternal attachment of the muscle is divided; and then the clavicular attachment, by repuncturing the integument in that situation. This precaution is safer than division of the muscle by one incision; as the two portions are not on the same plane, and passage of

the knife to a sufficient depth for that purpose would be dangerous. Complete division is accompanied by a very sensible crack, and some alteration in the attitude of the head. Immediately after operation, Dr. Little found the difference in length between the affected and sound muscle reduced more than one-half.

FIG. 221.

The advantage gained by the operation, must be followed up by mechanical means to maintain and gradually complete the readjustment of the head in position; otherwise, the divided portions of muscle reunite, and the deformity returns. An apparatus invented by Mr. Bigg (Fig. 221) best answers this purpose; by counteracting any tendency of the head downwards, sideways, and outwards, and thereby restoring it to its vertical position and the chin to the middle line. Dr. Little highly commends cautious manipulation daily, as well as the use of a retentive apparatus. This after-treatment must be continued for a period varying from one to three months, when permanent cures have been accomplished.

Paralytic wry-neck may be rectified by strychnine, electricity, and other measures for the restoration of nervo-muscular action. A steel-spring cravat or other contrivance for supporting the head, is the only mechanical resource available.

Disease of the cervical vertebræ, as the cause of wry-neck, can be remedied only by the measures—medicinal, dietetic, and hygienic—appropriate for the particular constitutional condition; and by wearing a well-adjusted, supporting, and slowly rectifying apparatus.

**STRABISMUS OR SQUINT.**—A want of parallelism in the axes of the eyes, whenever both are directed to an object at the same time. This habitual mal-position of the eyes results from irregular action of the internal or external rectus muscle; the one producing *convergent* strabismus—the eye being directed towards the nose; the *divergent* strabismus—the eye being directed towards the temple. Either form of strabismus may be *single*; *double*, when both eyes converge or diverge. The latter direction is rare, and consequent on loss of sight in one eye, which has lasted for years.

**Causes.**—Strabismus may arise from a cause remote in some distant part of the body, of which the squint is symptomatic; or from various local conditions pertaining to the eye; but more frequently from the former class of causes. Thus, this affection may arise from intestinal irritation or teething; or from disease of, or relating to, the brain, as hydrocephalus. It may be consequent on certain blood conditions, as measles or scarlatina, among the eruptive fevers. Inflammatory, or other diseases, of the eyeball, conjunctiva or eyelids. Extreme shortness of

sight, compelling the patient to converge both eyes in looking at near objects, may induce strabismus; and it sometimes results from the influence of insensible imitation.

*Treatment.*—Removal of the cause, in any case, will probably restore the regular and equal action of the recti muscles. Hence, any source of irritation in the intestinal canal or elsewhere, should be sought for, and removed, if practicable. Persistent causes render this principle of treatment impracticable, and strabismus must then be rectified as an effect, by division of the contracting muscle. This operation, first introduced in 1810, has since been modified. It now consists in *sub-conjunctival* division of the muscle affected; commonly the internal rectus. The details of this procedure are described in the chapter on Diseases of the Eye.

DEFORMITIES OF ARM AND HAND.—Contraction of the muscles of the upper extremity differs from those of the lower extremity, in so far as the individual muscles of their analogous parts perform functional movements, more delicate, varied, and complex. Various muscles may be affected, producing deformities which correspond to their respective functions. Thus, contraction of the biceps, with permanent flexion of the arm, or the extensors of the forearm, the flexors of the fingers, or those of the wrist, or the pronators; may be severally engaged. As affecting the fingers, muscular contractions produce forms of *club-hand*.

The *causes* of these contractions, and resulting deformities, are either spasmodic or paralytic conditions; and as depending on some injury or disease affecting the nervous system peripherally or centrally.

*Treatment* must have reference, primarily, to removal of the cause of contraction or paralysis, if possible. But the state of contraction, as an effect, may be overcome mechanically; by manipulations, or by division of the contracted muscle or muscles, or their tendons—the operation of tenotomy; followed, in either case, by the use of retentive appliances.

The choice of these two procedures will be determined by the kind and degree of motion to be regained in the part, and by the practicability of aiding recovery by means of any apparatus.

Thus, according to Dr. Little's experience, the biceps at the bend of the elbow, the tendons of the flexor carpi radialis and ulnaris close to the wrist, and the pronator radii teres at its muscular portion, have been severally divided in different cases; but the resulting benefit of these procedures has been proportionate to the after-manipulations, passive exercises, and painstaking education of the enfeebled non-contracted extensors. The fingers derive little benefit from any limited degree of the simple movements of flexion and extension, nor can they be assisted by any known form of mechanism.

*Contraction of the Fingers from disease of the palmar fascia*, should be distinguished from contraction of nervo-muscular origin. The pathology of this condition was discovered, on dissection, by Dupuytren and Goyrand.

It results not unfrequently from habitual pressure on the palm of the hand, as in bearing on a knob-headed walking-stick, or using an instrument which has this effect, in the exercise of various trades. Or, without any apparent exciting cause, a rheumatic or gouty diathesis may give rise to chronic thickening of the palmar fascia, in the form of projecting ridges extending from the palm to the contracted fingers. (Fig. 222.)

The *treatment* is, in principle, the same; division, subcutaneously, of any tense *fascial* prolongations binding down the fingers. Sometimes,

firm adhesion of the skin to these bands necessitates its separation, by a long incision and dissection of the skin back on either side; the bands must then be divided or dissected off the tendons, leaving their sheaths intact. After either operation, the fingers are to be straightened and retained in position on a splint.

FIG. 222.

*Congenital Deformities of the Fingers* may be met with. Erichsen saw a case in which the fingers appeared as if they had undergone complete or partial amputation *in utero*. Some were marked by deep transverse sulci, others shortened and terminating in rounded nodules, with a narrow pedicle attaching them to the proximal phalanx. *Supplementary* fingers, or a thumb, are also met with. (Fig. 223.)

FIG. 223.

DEFORMITIES OF LEG.  
—(1) *Knock-knee* or *In-knee* — *Genu Valgum*. —

This deformity is an inward yielding of the knee-joint, the result of weakness of the ligaments and muscles which support the joint in that direction. It occurs not unfrequently, and usually both knees are affected; giving the person a singularly ungraceful attitude when standing, and in walking the knees knock and roll over each other with a shuffling gait.

The *causes* of knock-knee are apparently *mechanical*; some occasion of undue strain on the knee. It mostly arises from trying to make a child walk too early, or it may occur in tall, rapidly-growing lads from the age of twelve to eighteen; in either case the knees yielding under the weight of the body. Habitual over-walking exercise or fatigue in standing, has the same result. Hence certain occupations are causative; and any habit of resting on one leg, or defect in the opposite limb, whereby an increased strain is thrown upon the sound limb; may induce this deformity. But, a rachitic tendency, or other *constitutional* condition of impaired nutrition, can often be traced as the predisposing cause.

*Treatment*.—Removal of the cause in operation, will sometimes prove sufficient. Thus, if the attempt to make a child walk at too early a period be discontinued, an incipient knock-knee may disappear.

*Mechanical support* is the only sure means of preventing further deformity, and of restoring the limb to a proper shape, by allowing the ligamentous structures to gain sufficient strength. The patient must be placed in “irons.” An iron stem, on the outside of the limb, extending from the trochanter to the outer ankle, is fixed by a pelvic band above, and into the boot below. A hinge in this rod at the knee allows of motion; while, by means of a leathern pad furnished with straps, applied on the inner side, the joint is secured to the stem above and below the hinge, and drawn outwards by tightening the straps. (Fig. 224.) The knee must thus be fixed during a period varying from three to six

months; then freedom of motion may be allowed for a part of each day during a similar period; and lastly, perfect freedom a few months before the support is discontinued. The total average duration of treatment, in advanced childhood and bad cases, will probably extend to two years.

*Division of the external lateral ligaments*, or of the *biceps tendon*, has been practised in obstinate cases; but this, or any cutting operation, is not now considered necessary. Constitutional treatment for the improvement of nutrition, will aid the mechanical cure.

FIG. 224.

FIG. 225.

FIG. 226.

(2) *Bowed, or Banded Legs*, present the opposite state of deformity of the Knees. (Fig. 225.) The *treatment* will consist in a form of apparatus to correct eversion of the Knee. The simplest is an inner lateral splint (Fig. 226), as a base opposed to the convexity of the curve.

(3) *Contraction of Knee-joint*.—Unconnected with disease of the joint, resulting in ankylosis with malposition; *simple* contraction of the knee is liable to occur. The deformity may be either, *flexion* of the leg on the thigh, at an angle of various degrees; or, combined with this state, some distortion *laterally* inwards, with rotation of the tibia outwards. Displacement *backwards* of the head of the tibia, the end of the femur and patella projecting forwards apparently, is associated with rather an extended position of the leg, and laxity of the joint.

FIG. 227.

The *cause* of these deformities—apart from joint disease—seems to be

some affection of the ham-string muscles, which induces their contraction, and shortening ultimately. This may be a purely *hysterical* manifestation, and accompanied with other symptoms of the same constitutional disease.

*Treatment* must have reference to the apparent cause of contraction. The more fugitive state of hysterical contraction, may perhaps be overcome under the relaxing influence of chloroform; the limb is then at once

FIG. 228.

brought down to a straight position, and retained by two lateral splints. (Fig. 227.) Or, reduction is gradually accomplished by a regulated extending apparatus. (Figs. 228, 229.) Division of the ham-string tendons

FIG. 229.

may be necessary, followed by extension. The biceps and semi-tendinosus always require division; the semi-membranosus, seldom. This renders the operation more superficial and simple than it would otherwise be.

**TALIPES OR CLUB-FOOT.**—Four forms of club-foot are recognised; *talipes equinus* or elevation of the heel; *talipes varus* or inversion of the foot; *talipes valgus* or eversion of the foot; and *talipes calcaneus* or depression of the heel with elevation of the anterior part of the foot. *Varieties* of club-foot consist of combinations of two of these forms, the principal of which are; equino-varus, equino-valgus, varo-equinus, calcaneo-varus, and calcaneo-valgus.

(1) *Talipes-equinus.*—*Structural Condition, and Signs.*—Certain bones of the tarsus—the astragalus, scaphoid bone, and calcaneum, have undergone alterations from their normal condition. Diminished in size somewhat; the astragalus, in particular, is reduced, its natural articular surfaces for the tibia and fibula are partially deprived of cartilage, and new articular relations have formed posteriorly, more or less in that

direction according to the degree of the talipes. The calcaneum may even contribute to this new articulation. The head of the astragalus, diminished in size, has an unusually small articular facet in its connexion with the scaphoid bone. This bone also reduced in size but unaltered in shape, is drawn downwards; thus presenting the head of the astragalus prominently on the dorsum of the foot, while a considerable portion of its upper surface has slid from under the tibia. The calcaneum small, and perhaps articulating with the tibia, has a more limited connexion with the cuboid bone; and as this bone, with the scaphoid, is drawn downwards, the anterior and upper portion of the calcaneum also projects forwards on the dorsum of the foot. The other bones of the foot, somewhat smaller than natural, retain their normal characters; the remaining tarsal and the metatarsal bones conform to the general curvature—an increased convexity forwards, an increased concavity backwards; but the toes are, usually, extended, horizontally.

Thus, then, the heel drawn up, in this form of talipes, brings the tarsus to nearly a vertical line under the tibia, whereby the weight is transmitted to the toes, on which the patient rests in standing or walking. (Fig. 230.) The ligaments are relaxed and shortened, corresponding to the altered relations of the bones; which facilitates the progress of the deformity, and impedes restoration of the foot to its natural position. The muscles, however, are the active agents in the production of talipes, one muscle or set of muscles overbalancing another and antagonistic muscle or muscles. In talipes equinus, the *gastrocnemius* muscle is contracted.

This form of talipes is usually single; but both feet are sometimes clubbed.

*Causes.*—The disturbed equilibrium of muscular action, in the production of club-foot, may be spasmodic, when referable to the contracted muscle; or be due to paralysis of the opponent muscle. Thus, in talipes equinus, spasmodic contraction of the *gastrocnemius*, may give rise to this deformity; or a paralytic state of the *tibialis anticus*, or of it and one or more of the other extensors of the foot, be the cause in question. *Exciting* causes comprise various sources of irritation, operating through the nervous system, as teething, intestinal worms; or some local irritation, as an inflammatory affection of the muscles of the calf of the leg.

Talipes equinus may be acquired or congenital; the latter very rarely, Tamplin, Lonsdale, and other authorities never having seen such a case.

*Treatment.*—Tenotomy is the only mode of cure. Division, subcutaneously, of the tendo-Achillis, allows the heel to be brought down; when the foot must be retained in position by a properly constructed extending apparatus.

FIG. 230.

The operation is simple. The patient having been laid prone, the Surgeon grasps the foot and extends it forcibly, thus making the tendon

Fig. 231.

tense and prominent; a tenotomy knife (Fig. 231) is introduced, at either side of the tendon, about an inch above its insertion into the calcaneum; passing beneath the tendon to its opposite side, the knife is withdrawn through the tendon slowly, its fibres yielding with a creaking resistance. The foot at once comes into position, or is readily brought down by extension with the hand, as the tendon is divided. Scarcely more than a drop or two of blood escapes externally, and the puncture is closed by a small piece of plaster.

Fig. 232.

The apparatus for extension is Scarpa's shoe, or its modification by Liston. Liston's shoe was provided with two curved levers. (Fig. 232.) The form of apparatus, or shoe, generally used for talipes equinus, is here represented. (Fig. 233.) It consists of a steel splint on the outer side of the

Fig. 233.

leg, with a foot support; both of which are secured by padded belts around the leg and foot. At the connexion of the splint and foot-board, a joint, worked by a key, regulates the extension.

Stromeyer postponed extension until the puncture-wound had healed; and then applied it gradually. The former rule is now obsolete in practice; the latter is observed by Little and most authorities. In my own more limited experience I have always employed gradual extension, after tenotomy. Union of the tendon becomes more perfect, and without entailing any risk of recurring deformity. Walking may be resumed as soon as union has taken place and the movements of the foot are regained, without any tendency to relapse; the period of rest required being, of course, much lessened by wearing the precautionary apparatus above described.

(2) *Talipes Varus*.—The pathology and treatment of this deformity much resembles that of talipes equinus.

The *structural condition* is similar, with regard to the alterations of the bones. But the muscles contracted are principally, the gastrocnemius, with also the tibialis anticus and posticus. The articular alterations, and the accompanying signs, are more like those of equinus, in proportion to the extension and curvature of the foot, which commonly occurs; but the foot is turned *inwards*, and this is the characteristic distinction. The patient walks on the outer side of the foot. (Fig. 234.)

The *causes* of this deformity would appear to be those of talipes equinus; but the varus form of talipes has been attributed to pressure of the walls of the uterus. It is certainly most frequently congenital;

almost as exclusively so as the equinus form is acquired talipes. Both feet, therefore, are usually affected.

FIG. 234.

*Treatment* consists, in subcutaneous division of the tendons of the contracted muscles; the tibial muscles, and the tendo-Achillis; followed by the use of Scarpa's shoe or Aveling's talivert (Fig. 235), to complete

FIG. 235.

the cure. By the latter apparatus, the three desiderata,—abduction, flexion, and retroversion, are obtained. A, metal shoe-piece; *d d*, lateral uprights of leg-splint; adjoining fig. *b*, etc., represents the extending apparatus.

In performing the operation of tenotomy, the posterior tibial artery, near the posterior tibial tendon behind the malleolus, is the only vessel liable to be injured; and with it, the companion nerve. This accident has happened in the most experienced hands; a compress and bandage will, mostly, arrest any hæmorrhage thence arising. In only one instance, has Dr. Little witnessed any evil consequence; a small filbert-sized aneurism requiring ligature of the vessel, three weeks after operation. A relapse, or rather conversion of the deformity into the opposite state, sometimes occurs; talipes valgus succeeding. In one case under my care, it was necessary to have recourse to the operation for that deformity. The shoe, most frequently used at the Royal Orthopædic

Hospital, is here shown. (Fig. 236.) Dr. Langaard's well-known instrument for talipes varus, is also deserving of notice. (Fig. 237.)

FIG. 236.

(3) *Talipes Valgus*—or *in-ankle*—presents the opposite arrangement of parts to that of talipes varus, and the peronei muscles are chiefly contracted. The foot is turned *outwards*, and possibly extended upwards, the patient standing or walking on the inner ankle. Thence also the knee inclines inwards, combining knock-knee with this form of

FIG. 237.

talipes.

*Flat* or *Splay-foot* presents the same characters as the above deformity; but, owing to relaxation of the ligaments in the sole of the foot, the arch sinks, and the foot is flattened.

The *causes* of talipes valgus have reference to the contracted muscles, and this deformity may be congenital or acquired.

Flat-foot is said to arise, in young persons, from long-continued standing or walking. I have seen it commence in girls who have suddenly become stout and heavy, about the age of puberty; the arch of the foot and inner ankle then giving way.

FIG. 238.

FIG. 239.

The *treatment* of talipes valgus must be conducted on the principles already laid down in the other forms of club-foot. Tenotomy will generally be necessary; and the tendons to be divided are those of the peronei muscles, and possibly also, of the extensor communis digitorum. The foot is then placed in a Scarpa's shoe. The best form of instrument is that devised by Dr. Langaard, of Hamburgh. (Fig. 238.) It is provided with a tangential ankle-screw.

Slight deformity of this kind can sometimes be corrected by extension, under the influence of chloroform; and subsequently wearing the shoe.

Flat-foot is amenable to the same plan of treatment, with the addition of a convex sole to restore and support the arch of the foot.

(4) *Talipes-calcaneus*.—Marked depression of the heel, and a corresponding extension upwards of the foot, characterize this deformity. The plantar arch may be contracted. (Fig. 239.) No structural alterations have taken place, but the deformity is simply symptomatic of muscular contraction; the muscles engaged being the four whose tendons pass between the two malleoli, anteriorly;—the tibialis anticus, extensor pollicis, extensor longus digitorum, and peroneus tertius, a part of the last-named muscle. The lateral ligaments, in their posterior portions, are much elongated.

This form of talipes is very rare, and was first described by Dr. Little, in the case of a child, four and a half years of age.

The treatment is much facilitated by the absence of any structural

FIG. 240.

FIG. 241.

impediments. Reduction can be easily accomplished by flexion alone, or aided by tenotomy; and the foot is readily retained in position. The best form of instrument, or shoe, for treatment mechanically, in order to restore the normal position and actions of the foot, is that shown in the annexed figure. (Fig. 240.) Bigg's apparatus is well adapted for cases of great severity. (Fig. 241.)

FIG. 242.

*Varieties of Club-foot*.—Combinations of the typical forms of club-foot are liable to occur. They have already been adverted to; but, to simplify the descriptions given, it was desirable not to introduce these varieties in connexion with their respective types.

*Equino-varus*, *equino-valgus*, *varo-equinus*, *calcaneo-varus*, and *calcaneo-valgus*, are modifications of the typical forms of club-foot. The particular muscles contracted will be suggested by each of these varieties of deformity. But the muscles engaged are declared by the tension and prominent rigidity of their tendons, as at once discovered by manipulative examination of the foot, in the various attitudes it has assumed.

Practically, this knowledge guides the appropriate orthopædic treatment; the manipulative extensions, the operations of tenotomy, and the mechanical appliances. For *equino-varus*,—to restore the foot to a normal position, Bigg's Orthopæde promises to be a valuable instrument. (Fig. 242.)

## CHAPTER XXXVII.

### EXCISIONAL SURGERY OF THE JOINTS, AND BONES.

#### THE JOINTS, FOR DISEASE.

EXCISIONAL SURGERY is best introduced by defining its full signification. Excision—or Resection, as it is sometimes less properly called—signifies the removal of any part of the body by a cutting-out operation of extirpation. This kind of operation relates chiefly to the joints and bones, although it may be practised also for the removal of tumours, as adventitious growths produced in connexion with the natural organism. The object of excision is, therefore, to preserve or to restore the organism, as far as possible, in or to its healthy anatomical integrity. With regard to the osseous system, comprising the joints and bones, excision may be practised either for disease or for injury of these parts.

In approaching this subject we may just take a retrospective glance at its history and time-honoured associations. Hippocrates, in whose writings 2400 years ago so many other surgical aspects of the present age are reflected, distinctly notices the resection of bones at the joints,—as of the leg, the ankle, the forearm, the wrist. Then, again, we find Celsus and Paulus Ægineta both as explicitly directing the excision of the ends of bone,—the one in compound dislocations, the other in compound fractures with protrusion. But the latter writer refers also to the practice of excision for disease of the joints or of the bones: “When,” says he, “the extremity of a bone near a joint is diseased it is to be sawn off: and often, if the whole of a bone, such as the ulna, radius, tibia, or the like, be diseased, it is to be taken out entire.” Thus, then, excisional surgery had its origin in that fertile period of the world's history when arts and literature flourished. Subsequently, in the course of those dark and dreary middle ages, when the human mind lay dormant, as in a death, it is scarcely possible to trace a vestige of that which was destined to become a leading feature of modern surgery. Not until towards the close of the last century were the operations of joint-excision fully recognised. In 1781, Park, of the Liverpool Hospital, excised the knee-joint, and with a successful result. This was followed by a second successful operation on the knee, in 1789. Contemporaneously, in France, the Moreaus, senior and junior, practised excision of this joint, between the years 1786 and 1789: and then of the elbow-joint, the one surgeon in 1794, the other in 1797.

The efforts of Park and Moreau failed to make any, the slightest, impression on the profession or the public. In September, 1782, Park wrote to Percival Pott, of St. Bartholomew's Hospital, "a few sheets, in which," said he, "I hope to show that in some of the affections of the knee and elbow in which amputation has hitherto been deemed indispensably necessary, surgery has yet another resource, which, as far as my reading and experience enable me to judge, has not yet been attempted by any other practitioner—I mean, *the total extirpation of the articulation*." He emphasized his suggestion by underscoring it, as an indication for italics. This announcement, however, seemed in no way to have moved the original mind of the famous metropolitan surgeon. On the Continent, the memoirs offered by the Moreaus to the French Academy provoked violent opposition, and were rejected with disdain by the surgical *savans* of France. Thus it was that towards the close of their labours the pioneers of excisional surgery experienced the mortification of knowing that they had attracted no followers—no successors.

It is unnecessary to pursue this general historical sketch further; those who revived the operations of excision, and subsequent contributors, will be amply noticed in connexion with the consideration of the several joints.

*Joint Excision in relation to the General Treatment of Joint Disease.*—In the pathological history or course of inflammatory joint-affections, certain general indications of Treatment may be recognised, which, in the order of their conservative or preservative character, admit of the following arrangement; and whereby the *relative* bearing of Excision, will become apparent.

The *Non-operative* indications comprise:—

(1) Preservation of the Joint, functionally, by restoration of its mobility.

(2) Preservation of the Joint, with loss of its mobility, by Anchylosis.

The *Operative* indications are:—

(3) Preservation of the Limb, and Life, by sacrifice of the Joint, with anchylosis—*Excision*.

(4) Preservation of the Life alone, by sacrifice of the Limb—*Amputation*.

The question of operative interference, it will thus be seen, can arise only when the joint-disease is already past the control of the first indication of treatment—restoration of the mobility and functional use of the joint; and when it has become subject to the second indication—preservation by anchylosis. But this result is also the object of Excision. The true comparison, therefore, of joint-excision for disease, is with the probability of *natural* cure by anchylosis. Such comparison should have reference, (1) to the joint, in respect to five essential particulars—the appropriate nature of the anchylosis or union, and the proper position of the limb for its functional use, the average duration of the periods of recovery, and the permanent character of that issue, with its average proportionate frequency; (2) the liability to life, or the comparative mortality of the natural cure by anchylosis and that resulting from excision, must also be considered. It may seem strange to speak of the mortality of the *natural cure*, for it might be said, that failing to obtain that issue in due time, the surgeon would interfere by an operation, either of excision or amputation, before death ensues. But the period of natural cure is very protracted, extending often to five years or more, and even to ten years. Cases of this duration respectively—not, it must be confessed, of a very

inviting and encouraging character, are recorded by Mr. T. Bryant and Mr. Hilton, as having occurred in their practice for the mechanical cure of knee-joint disease. But even a more important consideration, is this—that such protracted recovery is attended with a proportionate reduction of constitutional vigour. Hence, with reference to the question of mortality, operative interference may be too late, or intercurrent disease consequent on delay, may carry off the patient; in either case, death ensues from the prolonged attempt to bring about a natural ankylosis.

Statistical results, bearing on all these questions, and which shall be sufficiently accurate and comprehensive, are yet wanting to determine the relative value of the two modes of cure—nature *versus* excision. Meanwhile, the fair and reasonable course to take surgically, in any advancing case of inflammatory joint-disease, is; to try for natural ankylosis by absolute rest and other proper treatment; and failing to obtain that issue, timely excision offers as a subsequent resource, under the conditions which are most favourable for a successful result to this operative procedure. What are they?

By an analysis of twenty carefully recorded typical cases, published in the Medico-Chirurgical Transactions of last year (1870), I endeavoured to establish three propositions, representing the conditions of disease appropriate for excision of the joints in general; and certain supplementary propositions relating to particular joints. The experience of eight additional cases enables me to confirm and enlarge these conclusions, and, so far as they may stand the test of further experience, they may be taken as principles or rules for the guidance of the surgeon in his selection of this operation. I may here state that this series of cases is *consecutive*—*i.e.*, it comprises *all* the cases in which I have had recourse to the operation of joint-excision. No adequate basis for generalization can be afforded by any limited series of cases; but my own have the advantage of preconsidered observation and analysis specially with a view to the purpose proposed; and I have supported my conclusions by large masses of evidence carefully gathered from recorded sources of trustworthy results.

#### GENERAL CONDITIONS OF DISEASED JOINTS APPROPRIATE FOR EXCISION.

—*Functional imutility* of a Joint, is the *resultant* condition for which the operation of Excision is appropriate; but as this may ensue either from persistent disease, or from failure of the natural cure, of a twofold character, it includes three general conditions, proper for the operation:—

*Firstly*,—as the result of persistent disease—destruction of the articular cartilages, with perhaps dislocation, without the supervention of ankylosis; but, whilst the *constitutional* condition has not advanced to hectic and emaciation.

*Secondly*,—as one result of the natural cure—Ankylosis, of a nature inappropriate to the functional use of the limb; being ligamentous where osseous union is required, as in the knee; or osseous where ligamentous-connexion is necessary, as in the elbow.

*Thirdly*,—as another result of the natural cure—Ankylosis, with mal-position of the limb. In the event of *fibrous* ankylosis, with mal-position; mechanical extension of the limb, tenotomy, or both these resources may be tried prior to excision of the joint.

Certain *subordinate* conditions, relative to the propriety of Joint-Excision for persistent disease, are less clearly established by an analysis of cases.

(1) The comparative eligibility of chronic synovitis or of scrofulous caries, would appear to be in favour of the former disease. Thus, in my knee-joint excisions; of the 12 cases, the 3 which required secondary amputation were cases of scrofulous caries; of the remaining 9 cases, 6 were synovitis, and 3 scrofulous caries.

Professor Humphry's experience is somewhat different—at least with regard to the knee-joint—prolonged scrofulous suppuration of the thickened synovial membrane having been the most frequent cause of failure after excision, in his cases. (*Medico-Chirurgical Trans.*, 1869.)

(2) A limited extent of osseous disease, would seem to be proportionately favourable for excision; but, one or both articular surfaces, or *ends* of bone, may be diseased. The disease must not extend beyond the limits necessary for the formation of sufficiently wide osseous surfaces for an adequately secure union, osseous or ligamentous according to the functional use of the limb. Or, the limits of diseased bone, with relation to excision, may have to be restricted for the preservation of a sufficient length of limb; and, consequently, for the preservation of the epiphyses or epiphysal cartilages, as affecting the subsequent growth of long bones, and thence of the limb. The epiphyses of the tibia and femur, in the knee-joint, for example, in relation to the growth in length of the lower limb, after excision of this joint.

(3) Disease of the soft parts around the joint diseased, is not, in itself, unfavourable to the result of excision; even although the integuments be much undermined by sinuses, and thickened by gelatinous infiltration, or soddened by puriform discharge. This surrounding condition of disease will subside, and the integuments regain a healthy state, when the central source of irritation, the diseased joint, is extirpated; provided only sufficient sound integument be left to cover the exposed ends of bone. But, advanced integumentary disease is generally connected with advanced constitutional disturbance and hectic exhaustion, the most unfavourable condition for joint-excision.

(4) A chronic state of disease, in the joint and surrounding soft parts, is a condition of far more favourable character for excision, than one of acute inflammation.

(5) In all doubtful cases, as to the diseased condition of the joint; a good practical rule is, to lay the articulation open, by an incision as for the operation, and examine its condition, before having recourse to amputation, which can then be performed at once.

(6) Certain co-existing constitutional diseases, as phthisis, seem to have an unfavourable influence, and in proportion to the progress of such disease.

(7) Age has no special constitutional relation to the propriety of joint-excision. Either extreme period of life seems unfavourable for this kind of operation, owing to the long period of recovery, averaging three months at least, for the knee or hip-joint; and six weeks for the elbow-joint. As to extremes of age; taking the knee-joint as the best example of a large joint; according to Dr. R. Hodges, excision has been performed as early as three years, and as late as sixty-eight years. The former case recovered, with what state of after-limb is not recorded; the latter died. The average age of the fatal cases was twenty-five years; of recoveries, nineteen years. Of my own cases, the first, and one of the most successful, was thirty-three years old, and another, equally successful, was twenty-seven. But, the constitutional power of recovery from

severe compound fracture, after either of these periods of life, would suggest the propriety of trying excisions at a more advanced age. *Youth* may be unfavourable for the operation, as being subject to an arrested growth of the limb, from removal of the epiphyses or epiphysal cartilages. But this objection relates only to knee-joint excision, the length of the arm, after operation at the elbow-joint, being comparatively unimportant; and even with regard to the lower limb, the line of epiphysal cartilage may not unfrequently be left, thus providing to some extent for the subsequent growth of the limb in length.

**OPERATION OF EXCISION.**—Certain general directions are common to all these operations.

*Instruments.*—The requisite Instruments, and Apparatus for after-treatment, are few and of simple construction. They comprise;—scalpels, thin and stout-bladed, curved copper spatulæ, saws—the common amputating saw and Butcher's saw, the chain-saw; gouges, and cutting plier-forceps, the lion-forceps for grasping bone, torsion-forceps, suture-needles, and silk or silver wire; splints and bandages, or other retentive apparatus.

This list of armamentaria might be extended, and many and complicated instruments are described, particularly by French authors. It would, however, appear doubtful whether some such appliances can possibly be used, in accordance with the design of Excision. Some, indeed, of the above-mentioned instruments are of restricted applicability, and come into use only occasionally. Thus, for joint-excision, the saw devised by Mr. Butcher, has a narrow blade, and being moveable, it can be adjusted at any angle; an advantage for running the saw easily, and in any direction, to finish off the excision. But, for the removal of an accessible slice of bone, the firm bearing of the ordinary broad-bladed amputating saw, is preferable. The chain-saw also will be requisite only under quite exceptional circumstances; as to get round an imbedded bone, and which cannot be exposed and turned out as usual, for application of the ordinary broad-bladed saw. This is a rare expedient, and I have never had occasion to resort to it, except in excision of the great trochanter; I have seen the chain-saw used in excision of the hip, but not with any apparent advantage; and once the instrument broke. The "lion-forceps," devised by Sir William Fergusson, enables the operator to gain a firm grip of the off-portion of bone, in order to steady it for the efficient and free working of the saw. This instrument thus proves serviceable in completing the excision of any partially severed portion of bone.

Ligatures are scarcely ever necessary for the arrest of hæmorrhage; torsion will generally prove sufficient. I have never found it necessary to apply a single ligature in any joint-excision; nor subsequently, but once, on account of secondary hæmorrhage. Silver wire is, perhaps, preferable to silk for sutures; the latter material being apparently more apt to induce suppuration, at the points of insertion along the line of incision.

(1) The *incisions* should be formed so as to fairly expose the articular ends of bone. Hence, they vary in shape according to the particular joint; a single linear incision, **I**, as frequently practised for exposure of the elbow-joint; a double rectangular incision, **—**, as also applicable to the same joint; or, as a **T** shaped incision, to the hip-joint; a curvilinear or elliptical incision, **U**, for the shoulder, perhaps the wrist, and the knee: or, an **H** shaped incision, as some Surgeons prefer for the latter joint;

and modifications of these incisions for the ankle-joint. The incisions are so placed as to avoid important parts—tendons, blood-vessels, and nerves; and, therefore, not in the flexure of joints.

(2) The ends of bone should not be denuded of their *integument* or of their *periosteum*, to any extent beyond the line necessary for the osseous excision; detachment of vascular connexion predisposing to necrosis.

(3) The *extent of bone* to be removed must be determined by observing the appearances of disease, compared with healthy bone, as discovered during the operation of excision. Hence, this kind of operation may be a piecemeal proceeding; as not unfrequently, in the elbow-joint. But, the results of reparation, in the production of osseous thickening, spiculated or nodular enlargement, must not be confounded with the results of disease. In *growing* long bones—*i.e.*, in young persons, joint-excision should not extend beyond the epiphyses, or at least the epiphysal cartilages, in the ends of bone, on which the further longitudinal growth of the bone—and thence of the limb, depends. The *sections* of bone should be parallel, so that the opposed osseous surfaces may be adjusted in apposition; a rule particularly important when osseous union is required, as in the knee.

(4) Skin, and subjacent integument, exclusive of thickened synovial membrane, rarely need be removed; the soft parts recovering a healthy state, and covering from exposure the ends of bone.

(5) *Hæmorrhage* may be arrested by torsion of the arterial vessels; ligature is rarely if ever requisite. Sponging with cold water will arrest any oozing hæmorrhage, and wash away any adherent particles of bone, or clots.

(6) The *ends of bone* must be placed in apposition, but not absolute contact—particularly when ligamentous union is required, as in the hip or elbow.

(7) The *attitude of the limb* must have regard to its functional uses, after excision of the joint. Thus, in the lower extremity, the hip-joint, and the knee, should be straight, for support of the trunk and for progression. In the upper extremity, the elbow-joint should be semi-flexed, to prevent osseous union, and to provide for the relative movements of the forearm and hand.

(8) *Retentive appliances* must have regard to the necessity, or otherwise, for a *fixed* position of the limb; according as the union required is osseous or ligamentous. A suitable splint or splints and bandaging must be applied, so as to prevent the liability of movement, in the directions of displacement peculiar to the joint, after excision; leaving the operation-wound accessible for dressing. This principle of treatment will be fully illustrated by the retentive appliances proper for each particular joint.

Finally, the *line of incision* is brought together and closed by sutures of silk or silver wire; care having been previously taken, at the very last, to see that any clot be washed out, and that the ends of bone are in apposition. Strips of lint soaked in water or weak carbolic lotion, are applied to the wound, and overlaid by a large piece of oil-silk; a bandage being applied over all, to further exclude the air, and maintain some compression for a time, to prevent oozing secondary hæmorrhage.

The *After-treatment* of Joint-Excision, is *local*, as relating to the process of union-integumentary, and between the ends of bone; and *constitutional* treatment, principally hygienic, as relating to the maintenance of

reparative power; both aspects of the treatment having regard also to occasional complications.

(1) Local after-treatment may be reduced to certain rules.—The integumentary wound undergoes more or less tumefaction, but it generally heals by the first intention—primary union taking place along the line of incision; except at its angles, which continue to discharge, slightly perhaps, a puriform matter, or lymph, when the ends of bone have long since united. The *first dressing* need not be removed, usually for 48 hours; then, the wound is to be cleansed, and similar dressing reapplied, the bandage being omitted, or applied lightly as inflammatory swelling supervenes. The *sutures*, some or all, may be allowed to remain for a week or ten days. The *retentive apparatus* should not be removed and reapplied for the first month after excision, unless absolutely necessary to correct some important displacement of the ends of bone. If osseous union be required this rule is the more imperative. The splints are reapplied at the end of another month, and so on; about three re-applications only being permitted in the course of osseous union, as of the knee-joint; while the splint may be abandoned, at a more early period, and passive motion commenced, when ligamentous union is required, as in the elbow. A starched bandage may be substituted for splints, when osseous union has become sufficiently firm; and thus enable the patient to get about and regain his general health. *Secondary hæmorrhage*, a rare complication after joint-excision, can generally be arrested by the ice-bag, or irrigation, aided by the compression of a bandage; and I have only once had occasion to reopen the wound to secure a bleeding vessel—and that in the knee-joint.

*Re-excision*, and *amputation*, will severally be considered in speaking of the different joints.

(2) Constitutional after-treatment should be equally free from the imputation of unnecessary interference. Guided by ordinary principles, little medicine-giving will be needed; the face gradually acquires a remarkable pallidity or sallowness, more than can be accounted for by the comparatively slight loss of blood at the operation; but this appearance wears off, under the influence of quinine and iron with a nourishing diet; the patient—supposing an excision in the lower limb, can often recline on a back-support in bed, so as to be enabled to read or write, or, if a female, amuse herself with needlework; and eventually, before leaving the bed, our patient has become the picture of health.

On the other hand, certain constitutional *complications* are apt to arise after excision, which are of an adverse, or even fatal, character. *Prolonged sickness* from the influence of chloroform, may be subdued by the hypodermic injection of morphia, in one-sixth of a grain doses, while life is supported by nutritive enemata. *Painful jerkings* of the limb; especially in young hysterical subjects, or in consequence of the attrition of the osseous surfaces, is another untoward event, which may be subdued in like manner. *Acute inflammatory fever* may arise, almost immediately after excision, especially in young subjects; but this subsides, or yields to ordinary treatment. *Pyæmia*, I have never yet known to occur after joint-excision. Severe rigors and acceleration of pulse, I have seen arise from attrition of the ends of bone; and in consequence of readjusting the splints, a month after excision of the knee-joint. But this paroxysm usually passes off. *Tetanus* has ensued in only one of my cases,—a knee-joint excision in a young girl of sixteen, and with a fatal result; the only death I have yet had after any joint-excision. *Echæm-*

tion, in consequence of prolonged suppurative discharge, is apt to ensue in scrofulous patients; and this complication will probably lead to re-excision, or amputation instead, or subsequent to this resource. Such cases of secondary amputation are often remarkably successful, in saving life, albeit the limb is sacrificed.

*Repair after Excision.*—Joint-Excision may not be followed by any process of reparation, the ends of bone remaining ununited, as in ununited fracture. Reparation ensues more commonly, however; and the process consists in the production of a substitute-tissue between the ends of bone, forming an intermediate union; which may be, either fibrous and flexible—as a ligamentous connexion, or an osseous and immovable union. *Ligamentous* union is accompanied with an adaptation of the ends of bone to each other, forming a new joint; as after successful excision of the elbow, an instance of which will be described subsequently, from a case recorded by Mr. Syme. *Osseous* union would appear to result from a transformation of the fibrous tissue by a species of ossification; but associated with the production of true cartilage, in the form of nodules, which as centres of development, also undergo ossification. How far the union may become, properly speaking, osseous, attaining to the minute structure of true bone, observations are wanting to determine. Any remaining portion of the original articular cartilage, after a partial excision, is not continuous with but quite distinct from the newly-produced ossifying cartilage; and the former undergoes fatty and fibrous degeneration, thus losing its cartilaginous appearance. The muscular attachments which had been severed by the osseous excision, probably regain new connexions around the united ends of bone; the tendon of the quadriceps extensor muscle, for instance, acquires an insertion into the end of the femur; while the soft parts around the joint become more or less thickened and indurated. Thus then, the union is fortified, and the limb adapted to resume its functional use.

This description of the process of osseous union accords with what was found to have taken place after excision of the knee-joint, in one of my cases, which was subjected to amputation in St. George's Hospital, ten months after the operation on the joint. The result of examination is given, as "repair after excision," in the Catalogue of the Hospital Museum; and a report also, in the Path. Soc. Trans., vol. xii. But the opportunities for such examination are necessarily few; in most cases, amputation of the limb is resorted to only when no appreciable reparation has commenced. The chief source of reparation is also uncertain. Ollier's observations, with those of Maisonneuve, show the importance of the periosteum, as the most active organ in osseous repair, rather than the bone-tissue or even the medullary membrane, and as being far more productive than the surrounding texture. The same relative importance, therefore, may be attributed to the periosteum in the process of repair after excision. Accordingly, I always carefully avoid detaching this membrane, and its vascular continuity with the textures around the ends of bone, which should be left embedded up to the surface of section.

*Excision compared with Amputation.*—Amputation of a limb is generally compared with excision of a joint for disease, as if the two were alternative operations. Now, the incurability of joint-disease by non-operative treatment is indeed the condition eligible either for excision or for amputation. But in what does such incurability consist? The whole diversity of opinion and experience among Surgeons in regard to the propriety of excision *versus* amputation springs from a twofold view of the

nature of the state in question. Thus, scrofulous disease of the knee-joint may be considered incurable, without operative interference, when the disease has advanced to destruction of the articular cartilaginous surfaces of the tibia and femur without the supervention of anchylosis, so that the joint has become functionally useless; or, the same disease may not be regarded as incurable until it has advanced to a further and even to an extreme state of disorganization—dislocation (partial or complete), abscess, sinuses, profuse and long-continued discharge, with the constitutional disturbance of hectic and exhaustion. The turning-point of distinction between these two opposite states of the same disease is this: in the one case the joint has become functionally useless; in the other, to this condition is generally superadded a constitutional state of exhaustion which leaves no period of time nor vital reserve-power sufficient for any prolonged process of reparation after operation—averaging three months for the knee and hip, and six weeks for the elbow.

But this measure of time and of reserve-power are the essential elements of that reparative process which will inevitably be necessary to effect osseous or ligamentous union, as the case may be, and thence a successful result after *excision*. Consequently, compared with *amputation*, the operation of excision, under the adverse circumstances of *advanced* disease, will be singularly unsuccessful; whilst, at an *early period*, recourse to amputation is unnecessary and unjustifiable.

Excision and amputation for joint-disease are, therefore, not alternative operations for the Surgeon's choice of one or the other. The comparatively early period for excision is too early for amputation, and the comparatively late period for amputation is too late for excision. When either operation becomes justifiable for joint-disease, the other should not be entertained.

The *Natural Cure* by Anchylolysis is the true standard of comparison for joint-excision, which, when successful, also results in Anchylolysis; and such comparison must have reference to the five essential particulars already mentioned (p. 607), and to the mortality.

The following *general results* of excision and their relation to conditions of disease of the joints, as illustrated by my own series of cases, may be here noted:

1. *Excision* proved successful by one operation, in 21 out of 25 cases of the knee, hip, and elbow-joints.

2. Of the 4 unsuccessful cases by one operation, 3 were cases of *scrofulous* disease, and of the knee-joint in a total of 12 cases; the remaining 1 being chronic synovitis, and of the elbow-joint in a total of 5 cases.

3. *Re-excision* was resorted to in 2 of the 4 cases; 1 knee-joint, and 1 elbow-joint, the latter with a successful result.

4. *Secondary amputation* in 3 of the 4 cases. All 3 were knee-joint cases, and subjects of scrofulous disease; 1 had been subjected to re-excision. The 3 amputations made *rapid recoveries*. These results tend to show that if the attempt to preserve a limb by previous excision, and even by re-excision of a large joint as the knee, should fail, the operation is not prejudicial to secondary amputation for the preservation of life.

5. *One death* only in the 25 cases, of the knee, hip, or elbow-joints, whatever had been the condition of disease, subject to the principles of selection laid down; or whatever the operation; excision, re-excision, or secondary amputation. The fatal case, was after excision of the knee-joint; and the cause of death,—acute tetanus.

**SPECIAL EXCISIONAL SURGERY OF THE JOINTS FOR DISEASE.—THE KNEE-JOINT.**—*The Conditions of Disease Appropriate for Excision.*—The knee-joint, considered in relation to the operation of excision, illustrates the three general rules as to the conditions proper for operation :—Destruction of the articular cartilages, and perhaps dislocation (Fig 243),

FIG. 243.\*

FIG. 244.†

without the supervention of ankylosis, but whilst the constitutional condition has not advanced to hectic and emaciation; ankylosis of a nature inappropriate to the functional use of the limb—namely, here, ligamentous union; or such ankylosis, coupled with malposition of the limb (Fig. 244) by retraction and dislocation.

But there are also certain *peculiar* conditions as pertaining to the knee-joint which more especially determine the propriety of excision.

(1) Compared with other joints, a certain *limit to the extent* of disease is essential to success. The disease must not extend in either the femur or the tibia beyond the limits requisite for the formation of sufficiently wide-based osseous surfaces to permanently support the weight of the body, and for the preservation of a sufficient length of limb to be really useful. The *patella* should always be removed, as being diseased in some cases, and always useless as a remnant after excision of the joint.

(2) In *young* subjects—under the age of about ten or twelve years—it is of importance that the disease should not extend beyond the limits necessary for the preservation of the epiphyses or of the epiphysal cartilages; the integrity of the latter, at least, being requisite for the subsequent growth of the bone, and thence of the limb, in length. The observations which led to this rule were originally made by Professor Humphry, of Cambridge.

\* Case 12 in my Series.

† Case 13, not included in the Series. In these, and all the Cases, the wood-engravings were drawn by Mr. C. D'Alton, from photographs.

*Operation.*—Excision of the knee-joint for disease, originally introduced by Filkin, of Northwick, in 1762, was followed by Park, of Liverpool, as an independent originator, in 1781; but the operation, performed by Syme in 1829, and on the Continent by Heyfelder in 1849, was revived by Sir William Fergusson in 1850, and followed immediately by Jones, of Jersey, and Mackenzie, of Edinburgh.

The patient lying recumbent, and under the influence of chloroform, the limb, already bent by retraction of the leg consequent on the joint disease, is firmly held by an assistant so as to present the knee vertically; his one hand grasping the thigh, the other hand the leg, the foot of which rests on the table. The knee-joint is most conveniently laid open for excision by a curved horseshoe-shaped incision (U), extending from the

FIG. 245.

side of one condyle downwards across the head of the tibia, just below its articular surface, to the same point on the side of the opposite condyle. Thus both ends of bone are exposed. A second sweep of the knife, dividing the ligamentum patellæ, will fairly enter the joint from side to side, when a touch or two over the remains of the crucial and lateral ligaments completely lays it open; the joint being at the same time forcibly flexed by the assistant. (Fig. 245.) In young subjects, with fibrous ankylosis, care must be taken to sever any such union with the knife, lest by forcible flexion either epiphysis become attached—an accident, in regard

to the tibial epiphysis, which happened in one of my own cases, and which my friend Mr. Bloxam, of St. Bartholomew's Hospital, has seen occur in two more. The joint having been laid open, I raise the flap of integument with my left hand, hooking my fingers under the patella, and, taking particular care not to detach the integument from the femur, I draw the knife across just above the articular end of bone, so as to define it for excision. The saw, a small, broad-bladed one (Fig. 246), is applied in this line, at a right

FIG. 246.

angle to the bone—observing to make allowance for the projecting direction of the articular end—upwards and forwards, in the flexed position of the limb, as held by the assistant. Unless this direction be observed, the section

of bone will be oblique to the shaft. A few *strokes* with the saw *brings* its edge out just behind the condyles of the femur, and corresponding to the posterior margin of the articular surface of the tibia; when a slight jerk outwards of the blade detaches the section, exposing a broad, flat, osseous surface on the end of the femur. The popliteal vessels and nerves are quite out of the way in making this section, the saw inclining forwards almost parallel with them, and the ligamentum posticum intervening. To make the tibial section, I apply the saw similarly in front of the head of the tibia, on the margin of the line of incision about half an inch below the articular surface, no detachment of the integument being necessary for this purpose, and carry the blade, at a right angle to the bone, or parallel to the articular surface, so as to bring the edge out about half an inch below it posteriorly; when a jerk upwards with the blade will detach the articular end without touching the ligamentum posticum, or endangering the popliteal vessels and nerves, and a broad, flat, osseous surface is exposed. Sometimes, the "lion-forceps" (Fig. 247), devised by Sir W.

FIG. 247.

Fergusson, is a useful instrument for the purpose of grasping firmly and holding steadily either articular section of bone, when nearly detached by the saw. And, this instrument may be equally serviceable in other joint-excisions. If the tibial section were made from *behind* the articular surface, and the femoral section also, as some Surgeons practise the operation, the popliteal parts would indeed be quite out of the way; but the ends of bone are thus apt to be detached from their vascular connexions, and the femoral section, as made from the front, is perfectly free from any risk, while the tibial section can be safely made with the little precaution already observed in using the saw towards the posterior ligament. But the liability of wounding the popliteal artery, either with the knife or the saw, should not be overlooked, that accident having happened in at least two instances, one of which was, however, a re-excision wherein the adjacent parts were somewhat affected by adhesion; yet, still to inculcate caution, this accident happened in the hands of a most skilful and practised operator. In the event of such a mishap, amputation must be performed forthwith. Excision of the joint may be performed in a *block*, instead of by separate section, when the articular ends of bone are firmly ankylosed; the piece of bone cut out having a **V** shape, owing to the projection of the knee forward from constant retraction of the leg.

The parallel surfaces of bone, thus made in either way, lie in parallel apposition when the limb is extended. This is the most important operative consideration with relation to the formation of firm osseous union. An oblique direction of either surface is most unfavourable to this result; too much space intervening at one part for the formation of an intermediate plate of bone, and the remainder of the surfaces being tightly locked, the limb cannot be flatly extended; painful startings of the limb

ensue from attrition of the surfaces in contact, and no intermediate plate of bone can be produced. Thus the union would be in part imperfect or ligamentous, and in part incomplete or wanting. A second section must be made from either end of bone, if necessary, to reach a healthy surface, or gouging may be requisite; but the extent of bone excised should be limited by the considerations already explained, and the surfaces must always be finished off *parallel*. The patella is removed, avoiding the making of a button-hole in the integument. Any thickened synovial membrane, often slate-coloured, may be dissected out. Hæmorrhage is easily arrested by torsion of the articular arteries, or any other small bleeding vessels. In scrofulous caries little difficulty is experienced. In chronic synovitis the bleeding is sometimes profuse, owing to the vascular and thickened state of the synovial membrane, and the bone remaining healthy and florid. But torsion, sponging with cold water, and exposure, will still prove sufficient to stop the hæmorrhage. I then extend the limb, and having seen that the ends of bone lie in even apposition—not absolute contact—a flat piece of sponge is held on the wound while the splints are applied. The extended limb is laid on a padded back-splint covered with oil-silk under the knee, this splint reaching from the fold of the nates to just above the heel. (Fig. 248.) I *now* prefer to have the foot-piece part of the lateral splint, as thus the heel escapes pressure and a consequent

FIG. 248.

tendency to sloughing. McIntyre's splint I have long disused: it not only causes some pressure on the heel, and precludes access to that part for dressing, if requisite, but the trough in which the limb lies induces more wasting of the muscles than would otherwise ensue, and thence also a loosening of the splint at an earlier period than when it may be safely removed for cleansing, and reapplied. Broad strips of adhesive plaster are drawn round the limb and splint, immediately above and below the knee, another broad strip high up on the thigh, and narrow strips around the ankle and instep. A roller bandage is applied from the foot upwards, and another high up from the thigh downwards, leaving the knee uncovered. An outside interrupted splint, well padded, and covered with oil-silk above and below the interruption at the knee, and provided with a vertical foot-piece, is now applied; this splint reaching from above the great trochanter downwards, and the end of the thigh-piece well supporting the very *end* of the femur externally, at the seat of excision, while the perpendicular foot-piece maintains the leg in position, and the upper end of the tibia in steady apposition with the femoral end of bone. Elevation of the whole limb five or six inches will be found to further aid the latter purpose. A short padded femoral splint may also be placed in front of the thigh, terminating just above the femoral end of the bone; but if the external thigh-piece be not *too wide*, this anterior splint will

scarcely be necessary, and I rarely use it. The external splint is secured by a roller bandage from the foot to below the knee, and by another bandage from above the knee, up the thigh, and over the end of the splint, with perhaps two or three turns around the pelvis. The use of the external splint is to counteract the tendency to displacement of the lower end of the femur, in three directions, after excision of the knee-joint—projection outwards by abduction, rotation outwards, and projection forwards.

The first two displacements give the characteristic bow-legged and twisted appearance which, in a greater or less degree, is so common in the course of union after knee-joint excision, and both of which proceed apparently from muscular action; while the tendency to projection forwards seems to be produced by a constant sinking of the buttock in bed, thus tilting the lower end of the femur forwards. The side-splint specially counteracts all three displacements; the thigh-piece corresponding in length and breadth with the femur, any tendency outwards is prevented; while eversion and forward projection are restrained by the bandage, and the latter displacement by the support of a firm mattress, or at least a pillow under the buttock. I have had occasion to lengthen this side-splint up to the axilla, so as to counteract a tendency to an angular twist of the trunk to the opposite side in bed; whereby the lower end of the thigh is abducted or everted, with an angular projection outwards at the knee. But there is no tendency to abutment inwards, and no occasion for the application of an internal splint, as practised by some Surgeons. Such a retentive appliance after knee-joint excision is the precaution of a blind timidity, not that which a due knowledge of the possible displacements would suggest.

Lastly, the sponge is removed from the excision wound, any clot wiped out, the ends of bone finally seen to be in apposition, and then the flap of integument closed down evenly by points of suture. Strips of lint soaked in carbolic acid lotion (1 part to 40) are laid over the line of incision, and a broad piece of oil-silk over the whole knee; over all a roller bandage is applied to further exclude the air, and maintain some compression to prevent oozing and secondary hæmorrhage. The patient is removed to a bed close at hand, the limb elevated on pillows to a height of about six inches, and a cradle placed over the excision.

*After-treatment* should be conducted in accordance with the general principles common to all joint-excisions. But I would urge the importance, with reference to the after-treatment of knee-joint excision in particular, of one rule: not to reapply the splints before the end of a month or six weeks, unless absolutely necessary to correct some important displacement. At that time, having removed the splints and gently raised the limb, I sponge it with a spirit-wash, which both cleanses, and fortifies the skin against the tendency to abrasion from pressure. This must be guarded against in reapplying the apparatus. At the end of another month's interval—the second month—on removing the splints, I gently test the progress of osseous union, by placing my finger over the line of union, and slightly moving the lower end of the leg up and down; the long leverage rendering any degree of movement at the union perceptible to the finger so placed, and even to the eye as a sort of hinge-motion. This test is far more delicate and painless than by grasping the limb above and below the knee, and moving it backwards and forwards; however gently that manipulation may be performed. At the end of the third

month, on removing the splints, the trial of union may be made, by seeing whether the patient can himself raise the limb a little from the bed, by its own muscular action. If so, a starched bandage may be applied, provided with a back-splint, and an external splint, of pasteboard; and the limb being slung from the neck by a long loop of roller-bandage, the patient may be allowed to get about on crutches to completely regain his general health. Apertures should be left in the starched bandage, opposite either end of the incision at the knee, where a small sinus-opening, at both points, often exists; and which may continue to weep for a considerable time. Don't probe these little openings. Any necrosed spiculum of bone will work its way out. Any subsequent displacement can be rectified before union is maturely consolidated; and the limb should be very gradually brought into use, for support and progression.

*Results of Excision of the Knee-joint in relation to Natural Anchylosis.*—The true comparison of joint-excision is with the natural cure by ankylosis. Such comparison would involve several essential particulars: the appropriate nature of the ankylosis, and with a proper position of the limb for its functional use; the duration of the period of recovery; the permanency of that result, and its frequency, as resulting from excision or from the natural cure; and their liability to life, or comparative mortality. Statistical results bearing on these questions, and which shall be sufficiently accurate and comprehensive for comparison, are wanting with regard to the knee-joint, no less than in respect to other joints.

Six valuable cases of knee-joint ankylosis, resulting from disease, without suppuration, have been recorded by Mr. T. Bryant.\* They do not, however, entirely meet the questions which I have suggested, and the limited number of cases do not supply sufficient data for comparison.

The period of natural cure would seem to be very protracted, extending often to five years or more, and even to ten years. Cases of this duration, respectively—not, it must be confessed, of a very inviting and encouraging character—are recorded by Mr. T. Bryant, and by Mr. Hilton as having occurred in their practice for the mechanical cure of knee-joint disease. But even a more important consideration is this, that such protracted recovery is attended with a proportionate reduction of constitutional vigour. Hence, with reference to the question of mortality, operative interference may be too late, or intercurrent disease, consequent on delay, may carry off the patient. In either case death ensues from the prolonged attempt to bring about a natural ankylosis. The patient is killed in the curing.

But this inquiry must be pursued. Its importance cannot be over-estimated, since, even in the advanced state of suppuration, free incisions into the joint may prove successful in terminating the disease, with a moveable joint, or at least with ankylosis—a mode of treatment in aid of the natural cure for which Surgery is indebted to Mr. Gay.

*Excision in relation to Life, or the Mortality after Operation.*—Taking the results of large collections of cases, those also in different Hospitals of the United Kingdom as smaller collections, and from the practice of individual Surgeons as still smaller numbers, three *general* conclusions may be established respecting the rate of mortality from knee-joint excision for disease:—1. A diminished mortality as the operation has continued to be practised. 2. Since the revival of the operation, and more recently, an average death-rate of 1 in 4 or 5 cases. 3. Very different death-rates in

\* Medical Times and Gazette, 1870.

the hands of individual Surgeons, varying from 1 in 2 or 3, to 1 in 12 and 1 in 19, or even less. The conditions of disease, both local and constitutional, in the cases selected for operation, have doubtless mainly determined this different resulting mortality, and not unimportant has been the mode of performing the operation, and more significant the after-treatment. But the operation and after-treatment in the particulars essential to success have, perhaps, chiefly affected the resulting state of the limb. The general results respecting the mortality of knee-joint excision for disease in large collections of cases, and those of different Hospitals in the United Kingdom during a period of the last five years, are exhibited in the following collections of cases, which illustrate the three general conclusions already referred to.

For the special returns relating to Hospitals (and to individual Surgeons), I am indebted to those whose names are stated below.

It is scarcely necessary to observe that, of the large total number of cases, some are necessarily included in more than one collection.

1. Collected by Mr. Butcher. Period 1850-54: Number of cases, 31: recoveries, 25; deaths, 6 (mortality, 1 in 5). Period 1854-56: Number of cases, 50: recoveries 41; deaths 9 (mortality, 1 in 5 or 6).

2. Collected by Mr. Price; period 1760-1860, extended by Mr. H. Smith to 1865.—Number of cases, 316: recoveries, 240; deaths, 76 (mortality per cent., 24·05, or 1 in 4). Amputations after excision, 39: recoveries, 30; deaths, 9.

3. Collected by Dr. MacCormac.—Number of cases, 74: recoveries, 49; deaths, 25. Amputations after excision, 11: recoveries, 7; deaths, 4.

4. Collected by Mr. W. P. Swain.—Number of cases, 82: recoveries, 67; deaths, 15. Amputations after excision, 4: recoveries, 4; deaths, 0.

5. Collected by Dr. R. Hodges.—Number of cases, 208: recoveries, 106; deaths, 60 (mortality per cent., 28·84, or 1 in 3 or 4). Amputations after excision, 42: recoveries, 7 (?); deaths, 9.

6. Collected by Heyfelder.—Number of cases, 213: recoveries, 149; deaths, 64.

7. Collected by M. L. Peniere (British and foreign); period 1762-1869.—Number of cases, 431: recoveries, 300; deaths, 131, including 47 amputations and 6 re-excisions.

#### *Author's Collection.*

1. King's College Hospital; period 1850-70. (Per Mr. H. Smith.)—Number of cases, 80: recoveries, 57; deaths, 23. Amputations after excision, 8; recoveries, 4; deaths, 4.

2. St. Bartholomew's Hospital; period 1866-70. (Per Mr. Callender.)—Number of cases, 37: recoveries, 28; deaths, 9. Amputations after excision, 3: recoveries, 2; 1 death.

3. Royal Infirmary, Edinburgh; period, 1865-9. (Per Mr. P. H. Watson.) Number of cases, 32: recoveries, 18; deaths, 14.

4. St. Thomas's Hospital; period 1866-70. (Per Mr. F. Churchill.)—Number of cases, 22: recoveries, 14; deaths, 4. There was one amputation after excision, which resulted in death. (Four cases under treatment.)

5. Royal Free Hospital.—Number of cases, 20: recoveries, 18; deaths, 2. Amputations after excision, 6, of which 3 were re-excisions; recoveries 6.

6. Chalmers Hospital, Edinburgh; period last six years. (Per Mr. P. H. Watson.)—Number of cases, 18; recoveries, 16; deaths, 2.

7. Royal Sea-Bathing Infirmary, Margate; period, last five years. (Per Mr. J. R. Clouting.) Number of cases, 13; recoveries, 10; deaths, 2; re-excisions, 2, no improvement. In 1 case, result not stated.

8. Charing Cross Hospital; period 1870. (Per Mr. Hancock.)—Number of cases 11: recoveries, 11 (?).

9. Royal Infirmary, Liverpool; period last five years. (Per Mr. W. J. Cleaver.)—Number of cases, 11: recoveries 10; 1 death. Amputations after excision, 3: recoveries, 3.

10. Westminster Hospital; period last five years. (Per Mr. F. Mason.)—Number of cases, 10: recoveries, 8; deaths, 2. There was one amputation after excision, which recovered.

11. London Hospital; period last five years. (Per Mr. M'Carthy.)—Number of cases, 8: recoveries, 5; deaths, 2; 1 progressing favourably.

12. Royal Albert Hospital, Devonport; period last five years. (Per Mr. W. P. Swain.)—Number of cases, 6: recoveries, 6. One amputation after excision, ending fatally.

13. Great Northern Hospital; period last five years. (Per Mr. J. Willis.)—Number of cases, 4: recoveries, 2; deaths, 2.

14. St. Mary's Hospital; period last five years. (Per Mr. Gascoyen.)—Number of cases, 2: 1 recovery; 1 death.

15. Guy's Hospital; period 1864–69, or five years. (Per Mr. T. Bryant, from Dr. Steel, Superintendent.)—Amputations after excision, 4: recoveries, 3; 1 death.

*Comparative Mortality of Excision, and Amputation in the Thigh.*—The results of thigh-amputation for disease, as noted in University College Hospital, are thus stated by Mr. Erichsen. Of 34 cases of such amputation, 7 died; or say 1 in 5—a mortality of 20½ per cent. Malgaigne's statistics from the Parisian Hospitals show a far higher mortality: in 153 cases of thigh-amputation for disease, 92 died, being a mortality of 60 per cent. Mr. Syme represents the mortality as yet higher—from 70 to 80 per cent., taking amputations of the thigh generally. Approaching larger masses of results, we find that in Mr. T. Bryant's collection of 1168 cases of thigh-amputation, 254 died, or 21·7 per cent.; and in Carrick's still larger collection of 1413 cases, 434 died—a mortality of 30·71 per cent., or 9 per cent. higher mortality than in the former series. These large collections of cases, however, are indiscriminate. They include excisions for injury as well as for disease, and the latter not exclusively such as might be eligible for excision. But Mr. Bryant has supplied 188 cases of amputation of the thigh for chronic disease of the knee-joint; and of these there were 41 deaths—1 death in between 4 and 5 cases, or a mortality of 21·8 per cent. This nearly corresponds to the death-rate first stated; and it about equals the death-rate after excision. But if the mortality of thigh-amputation, and of excision of the knee-joint, both for disease of the joint, be thus about equal, the patients who survive either operation have a very different advantage; the one being without a limb, the other with the limb preserved.

*State of the Limb.*—The functional result of excision, whether of the knee-joint or other joints, is generally expressed in rather vague terms—*e.g.*, useful limb, without specifying the kind of union, or the position of the limb, as straight or bent. This indefinite mode of record omits much satisfactory information as to the state of the limb after operation. As a

specimen of the average record of results under this head, I may cite from Mr. Butcher's collection of cases referred to in considering the relation of knee-joint excision to the mortality after operation. Of the 25 recoveries, out of 31 cases, 17 were enabled to walk about with "perfect use" of the limb. Of the 41 recoveries, out of 50 cases, 33 had "useful limbs," the remaining 7 being subjected to amputation.

Compared with the stump after amputation, Sir William Fergusson justly observes:—"A well-healed stump never in reality improves, unless, possibly, it gets more callous, whilst often it gets more tender and irritable; but the seeming perfect result of excision at the end of six or twelve months, just when stumps are generally at the best, is no criterion of true perfection. If the limb is properly managed afterwards, it goes on improving for months—ay, for years. The thigh, leg, and foot enlarge in bulk; and in particular, with this change, the leg and foot improve in muscular energy." But why draw any further comparison between a stump—a truncated limb, and a slightly shortened limb, even although the stump be fitted and set off with an artificial leg?

The *average duration* of the progress of recovery is considerable. According to Dr. Hodges' tables, the duration of treatment, when the patella had been removed, in 48 cases, was 225 days; and when that bone is believed to have been left, in 38 cases, this period extended to 255 days. The average duration, therefore, was about eight months. But in 8 successful cases, all of them children, at St. Thomas's Hospital, the average duration of treatment, as reported by Mr. Allingham, was only 206 days, or about seven months. Many cases also progress more rapidly than this; and in my first case of excision of the knee the period of osseous union was only 60 days, or two months, the knee then supporting the weight of the trunk. This patient was thirty-three years old at the time of operation, with previous synovial disease of six years' duration; and the union has stood the test of twelve years' free use of the limb. The *average period* for recovery, in my own cases, has been, for the production of firm or perhaps osseous union, three months; and to regain a useful limb, three months more, in a starched bandage, with gentle use of the limb gradually, for support and progression. Subsequently the limb will regain bulk and strength by increasing muscular development.

The *permanent character* of a successful result after excision, and the *average frequency* of such result, are questions severally omitted from statistical records. Both these important elements are noted in the results of my own cases. (See *Analysis*, p. 629.)

The *growth of the limb* in length, after excision of the knee-joint, is a question respecting which the results are conflicting. The question can only affect the propriety of this operation in *youth or childhood*. It was originally suggested and investigated by Professor Humphry, of Cambridge, in an admirable paper on the Growth of Bones in their Long Axis at their Epiphysial Cartilages. The two epiphyses—upper and lower—in a long bone are not equally productive of its longitudinal growth; one is a more active organ of growth than the other. In the tibia and humerus the upper epiphysis is thus more important; in the femur and radius, the lower epiphysis. But the lower femoral epiphysis would appear to be *relatively* more important to the longitudinal growth of the femur than the upper tibial epiphysis is to the elongation of the tibia. Hence, with reference to excision of the knee-joint, removal of the *femoral epiphysis* will more especially arrest the subsequent growth of the

limb in length. The growth of the *foot* also is arrested, so that it may become insufficient to sustain the weight of the body. All this arrest of development may be reduced still further by the imperfect growth from previous disease.

The practical deduction, therefore, seemed to be, that if, by excision of the knee in a growing subject, the epiphyses and epiphysal cartilages of the tibia and femur be removed, this operation will *invariably* tend to arrest the growth of the limb subsequently. Mr. Pemberton, of Birmingham, followed, in 1859, with a case in which a youth, having been operated on in 1854, the limb in 1859 was nine inches shorter than its fellow. Another case, from the practice of Dr. Keith, of Aberdeen, showed a deficiency in length of five inches during six years' growth. Counter-evidence on this question is adduced by Mr. Butcher. Dr. Keith himself wrote to the latter eminent Surgeon, in 1856, that "J. Hay's limb, operated on November, 1853, is plump, and growing in length as fast as his sound limb. So also is J. Keith's, operated on May, 1854." Corroborative cases are cited from reports by Mr. Page, of Carlisle, and Mr. Brotherston. In a case where the entire epiphyses were removed by Mr. C. Heath from the knee-joint of a boy aged eleven years and a half, subsequent measurements showed that the *loss* of growth in length of the limb, was only two inches in five years and a half. This case also illustrated the fact that such arrest of growth depends more on the removal of the lower epiphysis of the femur than the upper epiphysis of the tibia, the one bone growing in length more than the other after removal of its epiphysis at the knee-joint. Thus, the femur, as compared with its fellow, had lost four inches; the tibia, compared with its fellow, had lost only half an inch,—making an absolute difference in the whole length of the limb of four inches and a half.

Still, allowing for these and other exceptional cases, the rule already laid down as to excision of the knee-joint in young subjects, under the age of about ten or twelve years, should be observed.

*Re-excision.*—This proceeding is particularly advocated by Sir William Fergusson. In his "Lectures on the Progress of Surgery" he urges re-excision after a fair trial of the result of the original operation. Then he observes: "I believe dealing freely with the wound, opening sinuses, clearing away strumous effete material, picking away loose necrosed pieces of bone, gouging away bare material of the kind—ay, even opening up the whole surfaces, and sawing off fresh pieces of bone, to be better than amputation." My own experience of re-excision, as to the knee-joint, may be thus summarily stated. In 12 cases of knee-joint excision, 1 was followed by re-excision, and 3 by secondary amputation, but with a recovery so rapid as seemed to indicate that neither of the previous operations, excision or re-excision, was prejudicial to secondary amputation for the preservation of life.

*Secondary Amputation.*—The probability of amputation becoming necessary after knee-joint excision is a question that may be determined by reference to the collections of results which I have brought forward, and which show also the mortality thence ensuing, in *addition* to the proportion of deaths arising from the operation of excision. Of the 7 cases alluded to in Mr. Butcher's report as having been subjected to amputation after excision had apparently failed, 6 recovered rapidly, and only 1 died. In my own cases, of 12 knee-joint excisions, 3, including the 1 re-excision case, were submitted to amputation, and all made rapid recoveries. Compared with *primary* amputation of the thigh for disease of the knee-joint,

these results as to mortality are most gratifying, and without at once sacrificing the limb which might yet be preserved by excision. Thus, in addition to the statistics already quoted, the mortality of primary amputation formerly at St. George's Hospital, as practised for "abscess" and "ulceration of the articular cartilages," was most melancholy. Of 11 such amputations of the thigh at that Hospital, as reported in the *Medical Times and Gazette* (1856), 5, or nearly 50 per cent., of the patients died, while 1 of the remaining 6 was convalescent only on the sixty-second day.

**TYPICAL CASES OF KNEE-JOINT EXCISION.**—In proceeding to record the essential particulars of my own series of knee-joint cases, it seems desirable to take them separately from the records of previous experience, in order to represent this series from two points of view,—firstly, as supplying *typical* illustrations of the conditions of disease, local and constitutional, which are appropriate for excision, and the results, proximate and permanent, of operation in each case, together with any peculiarities; secondly, the cases are submitted to analysis with reference to these, and also any *questions* of secondary importance pertaining to excision of the knee-joint for disease.

Two of the cases were partly narrated in the Hospital Reports of The Lancet of 1860; the remaining ten cases I have abstracted from clinical notes carefully taken by Mr. T. C. Murphy, senior house-surgeon at the Royal Free Hospital.

The first four cases especially illustrate the conditions of disease which I have found to be appropriate for excision of the knee-joint—during the course of disease; in three other cases, 7, 8, and 9, as being failures of the natural cure, both in regard to the kind of ankylosis and by malposition of the limb. The remaining 5 cases are interesting more particularly as exhibiting peculiarities or complications: in one case, albuminuria; in another case, a very early period of life; in another, pregnancy at the time of excision, but safe parturition at the full period, with a living, healthy child, and the mother's limb having undergone firm osseous union; in another, accidental detachment of the tibial epiphysis in the operation; in another, acute tetanus and death,—the only fatal case I have yet had after *any* joint-excision, 28 in number.

**CASE 1.**—Elizabeth D—, æt. 33, admitted into the Royal Free Hospital on the 12th of September, 1859. *Chronic synovitis* of the right knee-joint, of traumatic origin (Fig. 249); duration of disease, six years; treatment occasionally. *Ulceration* of the articular cartilages, and extensive *caries* of the ends of the femur and tibia. Constitutional condition, nervous exhaustion. *Excision.* *Recovery*, with firm osseous union and a thoroughly useful limb in two months. *Result* known to be permanent after ten years. (See Fig. 249.)

**CASE 2.**—William A—, æt. 27, admitted into the Hospital, July, 1869. *Chronic synovitis* of the left knee, apparently of constitutional origin; five years' duration; four months' treatment. Pulpy thickening of synovial membrane. *Ulceration* of the articular cartilages, and superficial *caries* of the ends of the femur and tibia. Health good. *Excision.* *Recovery*, with firm osseous union and a useful limb in three months. Subsequently, limb slightly bowed.

**CASE 3.**—John P—, æt. 18, admitted into the Hospital Oct. 19th, 1859. *Scrophulous caries* of the ends of the femur and the tibia in the right knee-joint, of traumatic origin; five and a half years' duration; two years' treatment, in five Metropolitan Hospitals. *Partial ulceration* of the

articular cartilages. Hectic and emaciation; this constitutional condition improved by medicine and diet, before operation. *Excision. Recovery*, with union in three months. At another Hospital, apparent recurrence of the disease after ten months. *Amputation*; rapid recovery.

FIG. 249.

CASE 4.—Emily R.—, æt. 20, admitted into the Hospital April, 1869. *Scrofulous caries* of the ends of the femur and the tibia in left knee, of traumatic origin; one year's duration; nine months' treatment. *Ulceration* of the articular cartilages. Health irregular. *Excision. Recovery*, with partly firm union, in three months. Formation of abscesses and sinuses around the callus, and prolonged discharge. *Amputation*, and recovery in a month.

CASE 5.—Sarah A. H.—, æt. 18; admitted into the Hospital, Feb. 2nd, 1869. *Scrofulous caries* of the ends of the femur and tibia, in the right knee-joint; of traumatic origin; twelve years' duration, with occasional treatment. *Ulceration* of the articular cartilages. Marked anæmia. *Excision. Secondary hæmorrhage* next day, suppressed by ice-bag. Displacement and projection of the end of the femur on the fifth day. *Re-excision* of its extremity. *Albuminous urine* supervened in a few days, with marked cachexia and prostration; and *sloughing* of the integument of the calf. *Amputation* in middle third of the thigh. Rapid disappearance of albumen in the urine, and restoration of strength. *Recovery* by primary union, with a perfectly sound stump in one month. About six months afterwards, stump still sound, but the patient was affected with scrofulous conjunctivitis and opacity of the cornea; also complete deafness.

CASE 6.—Elizabeth A. G.—, æt. 5; admitted into the Hospital, July, 1869. *Scrofulous caries* of the ends of the femur and tibia, especially the latter, in the left knee-joint of a child; of supposed traumatic origin; three and a half years' duration, and occasional treatment; *ulceration* of

the articular cartilages. Health good. *Excision* through the epiphyses. *Recovery*, with firm osseous union and a useful limb in four months.

CASE 7.—Henry G——, æt. 20, admitted into the Hospital, Oct. 28th, 1869. *Chronic synovitis* of the left knee-joint, of traumatic origin; one year's duration; ten months' treatment. Partial ulceration of the articular cartilages of the femur and tibia, followed by partial *fibrous ankylosis* and retraction of the leg, with *partial dislocation* of the femur forwards. Health good. *Useless tenotomy* of the hamstring muscles. *Excision*. *Recovery*, with a thoroughly firm osseous union and useful limb in two months and a half. *Permanent result*, one year. (Fig. 250.)

FIG. 250.

FIG. 251.

CASE 8.—Henry H——, æt. 17; admitted into the Hospital Nov. 27th, 1869. *Scrofulous caries* of right knee-joint, of traumatic origin; fourteen years' duration, with occasional treatment. Partial ulceration of the articular cartilages of the femur and tibia, followed by partial *fibrous ankylosis* and retraction of the leg, with *partial dislocation* of the femur forwards. Health good. *Useless tenotomy* of the hamstring muscles. *Excision*. *Recovery*, with osseous union and a useful limb in two months. This patient sat up out of bed daily at the end of five weeks. *Permanent result*. Nine months after operation (Dec. 1870) he could stand on the one leg unsupported, and hop on it; just before Christmas he walked from near Gray's-inn-road to Harrow and back—a distance of twenty-four miles—for a day's bird-snaring; and on Boxing-day he was sliding on the ice all day. Continued result, one and a quarter year after operation. (Fig. 251.)

CASE 9.—Thomas W——, æt. 10; admitted into the Hospital, Oct. 1869. *Scrofulous caries* of left knee-joint, of traumatic origin; seven years' duration and equally prolonged treatment, latterly by *extension* of the limb. Partial ulceration of the articular cartilages of the femur and tibia, followed by partial *fibrous ankylosis* and retraction of the leg, with

*partial dislocation of the femur forwards. Health delicate, with constant cough. Excision through the epiphyses. Recovery, with osseous union and a useful limb in two months and a half. Permanent result, one and a quarter year. (Fig. 252.)*

FIG. 252.

CASE 10.—Sarah S——, æt. 20. *Chronic synovitis of the right knee-joint, of traumatic origin, by a fall off a form. Duration of disease, fourteen years. Treatment in two Metropolitan Hospitals at different periods up to fifteen years of age. At both these institutions amputation of the thigh was declared imperative. Extensive ulceration of the articular cartilages of the femur and tibia; limited fibrous ankylosis, with retraction of the leg to an angle of sixty degrees; ankylosis of the patella to the condyles of the femur. Health reduced; pregnancy of one month. Excision. The night of operation, sickness from chloroform. For two days, painful startings and jumpings in the leg of spasmodic character, affecting the knee. Fourth day, an hysterical fit, and the startings were renewed. The usual apparatus—a long back splint, and an external interrupted splint with foot-piece—holds firmly, and no displacement of the ends of bone. Spasms subdued, and sleep induced by the hypodermic injection of morphia—one-sixth-grain doses occasionally. Two months and one week after operation, “quickenings” was first felt. The incision was firmly healed by primary union, and firm ankylosis between the ends of bone progressing. Puffy swelling around knee; reduced by moderate and gradual compression with a many-tailed bandage. On removing the splints, a small ulcer on the heel, and another on the sharp edge of the tibia. Apparatus reapplied, leaving the heel more uncovered, and an opening opposite the tibial ulcer. Under zinc-wash dressings, both sores healed. General health very good; the patient fast regaining flesh and colour, with a bright eye and cheerful aspect—looking, indeed, the picture of health. Recovery, with firm fibrous ankylosis, in*

three months; limb put up in a starched bandage, and the patient allowed to get about on crutches. Shortly after, was discharged from the Hospital. A tendency to bowing outwards of the knee was soon evinced; rectified by gradual manipulation, the imperfectly ossified callus admitting of such *readjustment*, and the starched bandage reapplied. *Parturition* at the full period; the mother and child both having done well. Firm osseous union. *Permanent result*, six months.

CASE 11.—Harriet M——, æt. 16. *Chronic synovitis* of the left knee-joint, of traumatic origin,—by a fall, and many years afterwards, by a puncture-wound with a crochet-needle two inches in depth, penetrating the joint. *Duration* of disease, thirteen years from first injury, six months from the second. *Treatment* commenced three years ago, continued for one year in a Metropolitan Hospital, then for some time in a special Hospital—where extension was long used without any permanent benefit. *Partial ulceration* of the articular cartilages of the femur and tibia; limited fibrous ankylosis, with retraction of the leg—the toes just touching the ground, and partial dislocation of the femur forwards. *Excision*. Sickness after chloroform. *Acute inflammatory fever* in twenty-four hours. Slight *rigors* on each of the two days following the operation. Third day, copious pink lithates deposit in urine, and subsidence of the fever. Sixth day, slight return of feverishness, and in the evening, *erythematous patches* appeared on the arms, front of chest, and neck, face flushed. This subsided in twenty-four hours, under treatment by bicarbonate of potash and tincture of hyoscyamus. Eleventh day, a *gangrenous patch of skin*, about the size of half-a-crown, in the middle line of the incision, which sloughed away in two days, exposing a portion of the femoral end of bone. All the sutures were now removed. Wound otherwise healthy, primary union taking place except in middle, and, as usual, at the angles. Ends of bone in perfect apposition. Sixteenth day, trismus, followed by full development of tetanus in twenty-four hours. At the end of thirty-six hours, death. Hydrate of chloral had been tried in ten-grain doses, every hour. P.-M. Examination of the joint—Union by tags of lymph, puriform fluid around ends of bone.

CASE 12.—William B——, æt. 9. *Chronic synovitis* of the left knee-joint, of traumatic origin, by a slight blow with a hoop. *Duration* of disease, ten months. *Treatment* in two Metropolitan Hospitals; and then in the Royal Free Hospital—by strapping, &c. Discharged; re-admitted in a month; *extension* by a back splint and screw, continued for five weeks without any effect. *Partial ulceration* of the articular cartilages of the femur and tibia; fibrous ankylosis, with retraction of the leg—the toes touching the ground, and partial dislocation of the femur forwards and outwards. *Excision*. *Accidental detachment of tibial epiphysis*, its removal, with the articular end of the femur through its epiphysis; also the patella. *Recovery* without a bad symptom. *Result*—Period since operation, five months.

ANALYSIS OF THE CASES.—(1) *Conditions of Disease*.—Caries in all cases, with the destruction of the articular cartilages of both the femur and tibia. In Case 1 the femur was chiefly affected, in Case 6 the tibia, and in the other ten cases both bones were about equally affected. The patella was healthy in nearly all cases.

(2) *Commencement of the disease*.—Synovitis in six cases—1, 2, 7, 10, 11, 12; scrofulous caries in the other six cases. *Cause*: Traumatic in eleven cases; constitutional in Case 2.

(3) *Duration of disease, and of treatment previous to operation.*—Case 1: disease 6 years; treatment occasionally. Case 2: disease 5 years; four months' treatment. Case 3: disease  $5\frac{1}{2}$  years; 2 years' treatment. Case 4: disease 1 year; 9 months' treatment. Case 5: disease 12 years; occasional treatment. Case 6: disease  $3\frac{1}{2}$  years; occasional treatment. Case 7: disease 1 year; 10 months' treatment. Case 8: disease 14 years; treatment occasionally. Case 9: disease 7 years; and equally prolonged treatment. Case 10: disease 14 years; treatment in two Metropolitan Hospitals. Case 11: disease 13 years; treatment 1 year in a Metropolitan Hospital, then in a special Hospital. Case 12: disease 10 months; treatment in two Metropolitan Hospitals, then in the Royal Free Hospital.

(4) The constitutional disorder had *not* advanced to hectic and emaciation in any of the twelve cases except in Case 3. In Case 1, nervous exhaustion; 2, health good; 4, health irregular, digestion impaired; 5, marked anæmia; 6, health good; 7, health good; 8, health good; 9, health delicate with constant cough; 10, health reduced; 11, health good; 12, health good.

Pregnancy, without miscarriage, at the time of excision; parturition at the full period, mother and child well; in Case 10.

(5) *Age and sex.*—Age: 33, 27, 18, 20, 18, 5, 20, 17, 10, 20, 16, and 9 years. Sex: six males and six females.

(6) *Operation.*—The *incision* was semilunar downwards from condyle to condyle in all the cases. The *portions of bone* excised were the articular ends of the femur and tibia in all the cases, with additional portions of cancellated bone in Cases 1 and 6. The patella was removed in all cases. The *synovial membrane* was also removed as much as possible in cases 2 and 7 of chronic synovitis. *Hæmorrhage* was inconsiderable during the operation in all the cases, no ligatures were required, the articular vessels being secured by torsion and exposure. *Sutures*—metallic in Case 1, silk in the subsequent eight cases. *Dressings*—water dressing in Cases 1 and 3, weak carbolic lotion in the other ten cases. *Splints*—a McIntyre, or else a back splint with foot-piece in all the nine cases, with an outside interrupted splint in all cases except 1 and 3.

(7) *Primary union.*—Complete, except just at angles of the incision, in Cases 2, 6, 7, 8, 9, 10, 12, or in seven cases; partial in Cases 1, 3, 4, 5, 11, or in five cases.

Secondary hæmorrhage in Cases 3, 5, and 8; arrested by ice in the first case, by ligature in the latter two. Sloughing or ulceration from pressure in two cases, 5 and 10.

(8) *Intervals of removal of splints.*—Average period one month after operation, and at similar periods subsequently; making only three or four reapplications of the retentive apparatus in each case.

(9) *Results.*—Osseous or firm union, and a straight limb, in all the cases; except Case 3, where it was incomplete; Cases 4 and 5, which were subjected to amputation; and Case 11, the *only death*, and from acute tetanus in thirty-six hours, seventeen days after operation. Period of union, average three months. Subsequently the limb slightly bowed in two cases—2 and 6; the latter a child aged five.

(10) *Re-excision* in Case 5—a scrofulous case.

(11) *Secondary amputation* in Cases 4 and 5—both scrofulous cases; also in the questionable Case 3—a scrofulous case.

(12) *Permanent result.*—Ultimate known period: (1) 11 years; (2)

1½ year; (6) 1½ year; (7) 1 year; (8) 1¼ year; (9) 1¼ year; (10) 6 months; (12) 5 months.

Such, then, at present, is the recorded contribution of the Royal Free Hospital to excisional surgery of the knee-joint for disease.

**HIP-JOINT.**—The *natural cure* of hip-joint disease has not yet been investigated in a series of cases, sufficiently accurate and comprehensive, for comparison with the results of excision. Such an inquiry should have regard, (1) to the joint, in respect to five essential particulars—the appropriate nature of the ankylosis, and the proper position of the limb for its functional use, the average duration of the period of recovery, and the permanent character of that issue, with its average frequency; (2) the liability to life or the mortality of the natural cure. It would be from these points of view, as to limb and life, that the results of excision must be compared and its relative value estimated. Pending this clinical inquiry, we may approach the question from our present knowledge of pathology.

What, then, are the changes which the joint and constitution undergo in the course of natural cure by ankylosis? In the joint there is a two-fold process of destruction and reparation. A piecemeal or molecular excision, so to speak, is constantly progressing, apparently by absorption and certainly by the draining away of débris of bone in the discharge until two healthy opposed surfaces are reached, so that union may at length be effected. This natural cure of joint-disease entails a protracted period of recovery, extending even to many years as compared with that of weeks or months required for recovery after excision. During this ordeal the constitutional vigour is reduced, subsequently leaving the patient stamped with the aspect of suffering in former years. Occurring also as it often does during the growing period of life, the reserve power, which should have been gained to meet the exigencies of after-life, is used up prematurely by incessant demand in the long process of reparative ankylosis. Persons who have undergone the natural cure of diseased hip-joint, for example, may be seen hobbling about the streets, being easily recognised by the characteristic gait of old-standing hip disease, and by their sallow and prematurely aged appearance. This constitutional decrepitude may possibly be averted by a remarkable acceleration of the excisional part of the process. In a case represented by specimen No. 7 of the hip-joint series, an eminent Surgeon differed with myself and others respecting its diagnosis; nature subsequently undertook the operation of excision *en masse*, for she severed and discharged the greater portion of the head of the femur through one of the fistulous tracks. This natural excision of a joint—one of the only two, I believe, on record—will be singularly suggestive to operative excisionists, and it should be equally admonitory to those Surgeons who blindly oppose the operation.

*The Conditions of Hip-joint Disease Appropriate for Excision.*—It was formerly held, and may still be maintained by some Surgeons, that Excision of the hip-joint for disease should be resorted to only in the following conditions—constitutional and local:—

(1) Only in the last stage of the disease, or of constitutional endurance.

(2) Only when the extent of disease is limited, the acetabulum being free from disease, and the amount of pelvic disease trivial.

(3) Only when the head of the femur is dislocated.

The reverse of these rules or nearly so may be partly gathered from

my cases, and can, I believe, be justified by accumulated experience, drawn from the results of a large but varying number of cases, with regard to each such rule in question.

Of the three conditions laid down respecting Excision of the Joints in general, the first only applies to the hip-joint.

(1) Destruction of the articular cartilages, without the supervention of ankylosis, will always justify operative interference by excision. The constitutional condition will probably *not* then have advanced to hectic and emaciation. (Fig. 253.) But the state of the general health should primarily determine the necessity for excision in all cases, and not any arbitrary consideration of the period of the disease and the condition of the joint. Whenever, therefore, the general health is manifestly failing, whatever may be the stage of the hip-joint disease, excision should be

FIG. 253.

resorted to and without further delay. This guiding rule was strongly urged and clearly illustrated by Mr. Hancock in his recent lectures at the Royal College of Surgeons. On the other hand, the most extreme state of constitutional exhaustion, previous to the operation of excision, may be followed by recovery after removal of the diseased bone; as the successful results in my own series of hip-joint cases, 1, 2, 4, and 6, clearly show.

(2) Osseous ankylosis with mal-position of the limb will *not* justify the peril of attempted excision. Section of the neck of the femur is practicable, whereby the limb can be brought down to a straight position. This principle of operation was lately practised in a case by Mr. W. Adams, and successfully.

(3) The *extent of bone* diseased may be considerable, and involve both the femur and acetabulum. In the *femur* the diseased portion may include the head, neck, great trochanter, and shaft, entering even into the medullary canal. In the *acetabulum* the diseased portion may include the whole floor of this cavity, and even extend to adjoining portions of the ilium, pubis, and ischium. Neither of these conditions of extensive osseous disease prohibits excision; but the acetabulum not unfrequently recovers itself when the diseased head of the femur has been removed from further contact and attrition.

(4) Dislocation is unfavourable for excision, as implying an advanced stage of the disease constitutionally. The significance of this local con-

dition will, therefore, diminish in proportion to the absence of marked hectic and emaciation.

The *evidence* in support of these principles or rules for hip-joint excision is important, seeing that they are at variance, as I have said, with the results of former experience.

Firstly, respecting the *constitutional condition*. Advanced hectic, inevitably consequent on prolonged irritation and suppurative discharge in the last stage of the disease, will evidently have so reduced or exhausted the patient's reserve-power, as to peril the prospect of recovery, although the diseased bone be then removed by excision. The deliberate postponement of the operation until that period when constitutional exhaustion with emaciation is verging on dissolution, would be almost equivalent to operating on a corpse. By analogy, I would liken it to the postponement of operation for the relief of strangulated hernia until the patient is sinking in consequence; the Surgeon deliberately allowing the expenditure of the reserve-power requisite for recovery, without which operative interference must necessarily be a failure and the patient doomed. Hey's maxim respecting strangulated hernia is at least suggestive with regard to excision:—"I have often had occasion to regret operating too late, I have never regretted operating too early." It is no answer to this argument for timely operation as the rule, to point to exceptional cases of successful results at a later period, in the obviously adverse condition of constitutional exhaustion.

*Osseous* ankylosis of the hip-joint, with useless mal-position of the limb, would seem to invite excision, to restore a straight limb and with a moveable joint; but the difficulty of detaching the firmly soldered femoral head from the acetabulum, or the damage done by this procedure, would be such as to render the operation impracticable or fatal. Section of the femur, between the trochanters, or in the neck, has been proposed and practised instead; operative procedures of which I shall have to speak in due time.

Respecting the *extent of bone* which may be excised successfully, this element in the operation of hip-joint excision does not appear among the tabulated particulars of the majority of cases recorded. The portions of bone removed in each of my own cases are stated in the analysis of the series. As to the *femur*, in one case, I excised four and a half inches of the bone,—namely, head, neck, great trochanter, and two inches of the shaft, with about one inch more of the cancellated bone below, thence entering the medullary canal. That is, I believe, the largest femoral portion of bone which has hitherto been removed in any case of hip-joint excision on record. The patient recovered, with a thoroughly useful limb, and permanent result at the end of five years. Sir W. Fergusson removed four inches of the femur in one case.

The *acetabulum* is very rarely the seat of origin in hip-joint disease, yet that portion of the articulation rarely remains unaffected. Of 92 cases, referred to by Mr. Hancock, in only 18 the acetabulum was healthy. But the head of the femur is mostly diseased in a greater degree, it having been entirely absorbed in 10 cases out of 143. In these 143 cases, also, the acetabulum was found more or less diseased in 119. In 10 cases an opening in the floor of the acetabulum communicated with the interior of the pelvis. In 4 cases perforation had taken place, and abscess within the pelvis. In 3 cases the acetabulum was trephined for the evacuation of pelvic abscess. Reparation may ensue in the diseased acetabulum,

when the head of the femur is removed from contact and attrition; as attested by the results of cases of dislocation consequent on disease, which in so advanced a condition must have involved the acetabulum. Or, the disease may progress to perforation, followed by pelvic abscess, and a fatal termination. The fair inference is, that excision will be rendered more safe by removing any diseased portion, or even the whole floor, of the cavity. Thus, the acetabular, and even the *pelvic* portions of bone removed, with success, have varied considerably in size. In 1 case Sir W. Fergusson removed nearly the whole of the acetabular cavity. In another case, Mr. Hancock removed the whole of the floor of the acetabulum, and the head of the femur. The patient recovered. In 1 case, Sayer, of New York, removed the acetabular cavity, with the spine and anterior crest of the ilium, as well as the head of the femur. The patient recovered. In another case, Mr. Bowman gouged the acetabulum, and the horizontal ramus of the pubes. The patient recovered. Lastly, Mr. Erichsen removed not only the whole floor of the acetabulum, but also the rami of the pubis and ischium, with part of the tuberosity of the ischium, and a portion of the dorsum ilii. The patient recovered. In my own cases, I have never had occasion to remove more than small portions of the acetabulum, which were scooped out in each case; the adjoining portion of the horizontal ramus of the pubes was denuded in one case, but it was left untouched and underwent repair. As a rule, I find, that superficial caries of any adjoining portion of pelvic bone is best left alone; rather than by groping about in the dark with a gouge, the vascular continuity of the integuments should be detached, and perhaps a portion of the carious surface may still be left unscraped. Nature, subsequently, completes the excision by molecular disintegration and discharge from the pelvic surface; with some prolongation only of the period of recovery, but with greater safety to the patient.

Lastly, *dislocation* is unfavourable, as implying an almost necessarily advanced stage of the disease constitutionally. Of 123 cases, more or less advanced to exhaustion, in 44 only, the head of the femur yet remained in the acetabulum.

*Operation.*—Excision of the hip-joint was originally proposed by White, of Manchester, in 1769, but the operation was first performed by Schmalz, of Pirnie, Saxony, in 1816; and first performed in this country, and for the second time in Europe, by Anthony White of the Westminster Hospital, in 1821; it was repeated by Hewson of Dublin, 1823; after which period the operation fell into disuse, until its revival by Sir William Fergusson, in 1845. Since that period it has been performed by many Surgeons, and in a large number of cases.

The hip-joint deeply placed, owing to the neck of the femur, is reached most conveniently by a T shaped incision; the vertical line, perhaps slightly curved, being made from just above the great trochanter downwards on the shaft to about three inches or less in extent (see Fig. 253), and the transverse line about half that extent on the summit of the longitudinal incision. The very limited extent of this latter incision avoids the femoral vessels anteriorly, and the crural nerve posteriorly. In disease of the joint, with perhaps consequent dislocation backwards on the dorsum ilii, and wasting as the result of long-standing disease, these incisions seem to be almost invited, so prominently does the trochanteric portion of the femur abut under the integument. By detaching the integument on either side of the vertical incision, keeping the knife turned towards the

femur especially on its inner side, the subjacent portion of femoral shaft is exposed; then, sinking the knife vertically in the transverse incision, just above the trochanter, the attachment of muscles thereto is divided; so that the finger can be readily passed down to the joint and its state ascertained. The capsular ligament will generally have given way or entirely disappeared. To turn out the remnant head of the femur for excision, it may be necessary to adduct and evert the limb, when with a touch of the knife on the bone, the round ligament yields and the head starts from its socket. Or, this ligament also may have disappeared, and the head and neck of the femur be so reduced, and the acetabulum so patulous, from more advanced disease, that the bone can be readily dislodged and hooked out with the finger. In a third class of cases, dislocation backwards has taken place. In any case, however, adduction of the limb across the opposite thigh presents the bone for application of the saw; and then the diseased portion is removed by one or more successive slices, the integument on either side being protected by a curved spatula. (Fig. 254.) The chain-saw may be used by those who prefer it. A gouge may be used to finish off the femoral excision; instead of unnecessarily removing any healthy portion of the trochanter, if that be left, or of the adjoining shaft. The acetabulum should be scraped rather than gouged, to remove any carious or denuded portion; or, more extensive pelvic excision may be necessary, and has proved successful. But superficial caries, acetabular or pelvic, will often recover itself, the former having been maintained by constant attrition of the femoral head. Any hæmorrhage is easily arrested by torsion. I have never had occasion to apply a single ligature in any hip-joint excision.

FIG. 254.

The limb can now be brought down straight, and a long interrupted-splint applied. Or, at first, the limb may be placed in an easy position on a pillow, and in the course of a few days, a long splint applied during the formation of flexible union. Or, guided by the pathological fact that this kind of union is required for the successful result of hip-joint excision, I have not used a splint from first to last, in any of my own cases. The healthy section end of the femur becomes drawn up, if dislocation has not already taken place, and the bone hitches on a healthy surface just out of the remnant acetabulum, where a sound fibrous ankylosis or false-joint is formed.

*Excision of the trochanter major* may occasionally prove sufficient; caries of this portion of the femur existing, without disease of the hip-joint. I have had one such case, and with a successful result.

The *after-treatment* of excision, whether of the hip-joint, or of the great trochanter alone, is very simple. The limb may be laid straight in bed, and retained in position only by a small side pillow, or roller sand-bag; without absolutely fixing the thigh. Or a long splint may be applied, extension being made from the opposite thigh, as recommended by Sir W. Fergusson. (Fig. 255.) Of these two modes of after-treat-

ment I prefer the former, especially for the joint-operation. The section-end of the femur is drawn up by muscular action, and hitches just above the acetabulum, which having been, generally, more or less superficially carious, is thus left to recover itself, undisturbed by any attrition of the femoral end of bone; while a new, and firmly fibrous, moveable joint forms, where the end of bone rests above the acetabulum. There is

FIG. 255.

little, or no, tendency to displacement after hip-joint excision, and the slight extra shortening which results from thus leaving the limb to itself, is unimportant compared with the advantages in regard to the acetabulum, and the formation of the best kind of new-joint requisite for the functional use of the limb, in progression, as well as for support. All my cases were treated in this way, and with perfect success.

*Results.*—(1) In relation to life or mortality. In 111 cases, collected by Dr. Hodges, of *unrecorded conditions* of operation; 56 recovered, 53 died from the combined effects of the operation and the previous disease; and in the remaining 2 cases, amputation was resorted to. Thus about 1 in 2 died,—a very high mortality. But Mr. Hancock presents the following very interesting results as to the mortality with reference to certain *guiding conditions* of disease for operation:—The *acetabulum* in a healthy state, gave a mortality of 6 in 18 cases, or 33 per cent. On the other hand, *acetabular disease* has had more favourable results of operation. Of the 10 cases in which perforation had taken place, 6, or 60 per cent., recovered; 2 only, or 20 per cent., died. Of the 4, in which not only perforation existed, but abscess also within the pelvis; 2 recovered, 2 died,—50 per cent. either way. Of the 3 in which the acetabulum was trephined for the evacuation of matter from the pelvis; 2, or 66 per cent., recovered; 1, or 33 per cent., died. Therefore, in the whole 20 of these apparently most unfavourable cases for excision, the mortality was only 5, 1 in 4, or 25 per cent. The relation of *pelvic disease* to mortality after operation, has already been noticed. *Dislocation* of the head of the femur having taken place; the percentage of recoveries was actually 46, against 23 where it had remained in its socket; the total number of cases compared being 143. Of my own 8 cases of hip-joint excision; in 4 there was dislocation, and they all recovered equally with the four in which dislocation had not occurred.

Another equally large series of cases—112, British and Foreign, has been collected by Dr. R. R. Good, late Surgeon in the Confederate American Army. This series is the more complete, as it embraces the most *essential particulars* respecting Excision of the hip-joint for disease, both in regard to its Mortality, and the state of the limb. We are thus enabled to take a commanding view of the whole subject; and in order

to observe the results, and their relationship more clearly, I have tabulated them.

*Tabular view* of 112 cases of Hip-joint-Excision, British and Foreign; Period 1860–8.

## MORTALITY.

*Collection of Cases by Dr. R. R. Good.*

- (1) Number of cases, 112.
- (2) Recoveries, 52, or 46·43 per cent.  
Deaths, 60, or 53·57 „  
Causes.—Exhaustion, 22. Phthisis, and progress of the disease, 10. Pyæmia, 5. Caries of the pelvis and purulent discharge, 4. Diarrhœa, 3. Exhaustion, with rapid pulmonary congestion, 2. Tubercular meningitis, tetanus, diphtheria, Amyloid degeneration of the organs, diffuse phlebitis of the limb, osteo-mylitis, hæmorrhage, acute necrosis of the femur, nervous collapse and pneumonia, each 1.
- (3) Disease, recorded in 29 cases.  
Scrofula, 3; 2 deaths, or 66·67. Cold, 4; 1 death, or 25·00.  
Injury, 20; 4 deaths, or 20·00. (2 cases not included.)
- (4) Duration previous to operation, recorded in 58 cases.  
Average duration, 2 years 3 months. In *acute* cases, or before 7 months; of 9 cases, 7 deaths or 77·77. In *chronic* cases, or 2 years and more; of 30 cases, 10 deaths, or 33·33; a balance in favour of chronic disease, 44·45.
- (5) Age, in the 52 recoveries; average, 11 years; extremes, were 2 „ years and 58 years.  
„ in the 60 deaths; average, 14 years; extremes, were 3 „ years and 40 years.  
„ from 2 to 12 years, 59 cases; 24 deaths, or 40·67.  
„ 12 to 20 years, 25 cases; 15 deaths, or 60·00.  
„ 20 to 58 years, 17 cases; 13 deaths, or 76·47.
- (6) Sex. 79 males.  
30 females.  
(3 sex unrecorded.)
- (7) Bone excised, recorded in 105 cases.
  - a Femur; section above great trochanter in 49 cases, 30 deaths, or 61·23. Section below great trochanter in 56 cases, 27 deaths, or 48·21. A balance in favour of section below,—13·01
  - b Acetabulum—*Diseased* in 72 cases, or 64·28. Deaths, 39, or 54·16.  
Abscess of pelvis, recorded in 6 cases; 2 deaths.  
Perforation in 11 cases (of the 72); 6 deaths, or 54·55.  
Perforated surgically in 5 cases (of the 72); 1 death, or 80·00.  
Gouged in 33 cases; 15 deaths, or 45·45.  
No interference in 6 cases; 5 deaths, or 83·33.  
—*Healthy* in 14 cases. Deaths 7, or 50·00. As compared with the mortality of diseased condition, 54·16; a balance of only 4·16 in favour of healthy condition.
- Dislocation, recorded in 17 cases; 6 deaths, or 35·29.  
As compared with *non*-dislocation in 93 cases; 52 deaths, or 55·92. A balance of 20·63 in favour of Dislocation.

<i>Countries.</i>		<i>Cases.</i>			<i>Deaths.</i>
Germany	...	34	...	...	22, or 64·71
England	...	32	...	...	11, or 34·37
America	...	29	...	...	13, or 44·83
France	...	14	...	...	12, or 85·71
Russia	...	3	...	...	2.

*Author's Collection.*

(1) Charing Cross Hospital; period, 1862-70. (Per Mr. Hancock.) Number of cases, 15; recoveries, 13; deaths, 2.

(2) Royal Free Hospital; period, 1863-70. Number of cases, 11; recoveries, 10; deaths, 1.

(3) King's College Hospital; period, last five years. (Per House-Surgeon.) Number of cases, 10; recoveries, 9; deaths, 1, six months after operation from tubercular meningitis.

(4) London Hospital; period, last five years. (Per Mr. J. McCarthy.) Number of cases, 10; recoveries, 4; deaths, 5; 1 progressing favourably.

(5) St. Thomas's Hospital; period, 1866-70. (Per Mr. F. Churchill.) Number of cases, 8; recoveries, 1; deaths, 5; 2 under treatment.

(6) Westminster Hospital; period, last five years. (Per Mr. F. Mason.) Number of cases, 6; recoveries, 6.

(7) Guy's Hospital; period, 1864-69. (Per Mr. T. Bryant, from Dr. Steel, Superintendent.) Number of cases, 6; recoveries, 5; deaths, 1.

(8) Liverpool Royal Infirmary; period, last five years. (Per Mr. W. J. Cleaver.) Number of cases, 4; recoveries, 3; deaths, 1.

(9) Great Northern Hospital; period, last five years. (Per Mr. J. Willis.) Number of cases, 3; recoveries, 3.

(10) Chalmers Hospital, Edinburgh; period, last six years. (Per Mr. P. H. Watson.) Number of cases, 3; recoveries, 1; deaths, 2.

(11) St. Mary's Hospital; period, last five years. (Per Mr. Gascoyen.) Number of cases, 2; recoveries, 2.

(12) Royal Albert Hospital, Devonport; period, last five years. (Per Mr. W. P. Swain.) Number of cases, 2; deaths, 2.

(13) Royal Sea Bathing Infirmary, Margate; period, last five years. (Per Mr. J. R. Clouting.) Number of cases, 1; deaths, 1.

(14) Royal Infirmary, Edinburgh; period, 1865-69. (Per Mr. P. H. Watson.) Number of cases, 1; deaths, 1.

(15) St. Bartholomew's Hospital; period, 1866-70. (Per Mr. Callender.) No cases.

Taking the results of the preceding collections of cases, three *general* conclusions may be established respecting the rate of mortality from Hip-joint excision, for disease:—(1) In different countries, a very different mortality, being highest in France, and lowest in England. (2) An average death-rate, of 1 in 4 or 5 (about the same as that of knee-joint excision, for disease). (3) Very different death-rates in the hands of individual Surgeons, British and Foreign—varying from, no mortality, to 1 in 2 or 3, 1 in 5, 2 in 3, 4 in 5, or even total mortality; thus differing far more extremely than the mortality of knee-joint excision for disease. It can scarcely be doubted that the conditions of disease, both local and constitutional, in the cases selected for excision, have mainly determined this different resulting mortality; although, the mode of performing the operation, and the after-treatment, have also been influential.

*Mortality compared with hip-joint Amputation.*—In 42 cases of amputation at the hip-joint for chronic disease; 24 recovered, and 18 died,—a mortality nearly as high as 1 in 2. It will be observed that the total number of cases here referred to is small, in proportion to the number of hip-joint excisions for disease. But the whole number of hip-joint amputations, hitherto published, is only about 126,—including the cases of injury and disease.

(2) *State of the Limb.*—In Dr. Hodges' collection of 111 cases, the 56 recovered "with more or less useful limbs." In Dr. Good's collection of 112 cases, of the 52 recoveries, 42 patients could use the limb, and in the remaining 10 cases, this result was not noted. The 42 cases are divided as follow:—

19	could walk without support.
9	„ with the help of a stick.
1	„ „ two sticks.
1	„ „ a splint
1	„ „ a crutch.
2	„ „ two crutches.
9	the manner of walking is not specified.

In 40 of the 52 recoveries, it was specially noted that the limb supported the weight of the body. In one case, crutches were necessary for this purpose, and in the remaining 11 cases, this particular was not noted. The movements in the new joint were reproduced in 28 cases, and in only 1 immovable ankylosis was the result. The ultimate period when the patients were seen after operation, varied from three months to five years. Their cure was ascertained, in most cases, after two or three years. Of the 52 cured, the average period of known permanent result, was nineteen months and four days. In my own 8 cases, the shortest period of known permanent cure was two and a half years; and the longest ascertained result, five years.

The *average duration of the period of recovery* has not generally been noted in the records of cases. In Dr. Hodges' collection of forty-nine cases wherein this particular was observed, the average was 230 days. In my own cases, the average period of *union* was three months.

In extreme cases of hip-joint excision—extreme as to the extent of bone removed—the resulting state of the limb may yet be successful. It was so in my own two such cases, after removal of the upper end of the femur, to four inches and four and a half in length, with one inch more of cancellated bone, and entering the medullary canal, in both cases; and, also in both the cases of acetabular and pelvic bone-disease, after removal of the affected portions of bone by Mr. Hancock and Mr. Erichsen respectively,—the patients recovering, and with useful limbs.

SECTION, rather than Excision, of the upper end of the femur, is a procedure which has been devised, and practised in a few instances, for failure of the natural cure,—osseous, instead of ligamentous, ankylosis of the joint, with useless mal-position of the limb, as by flexure on the thigh and abduction. This condition, calling for operative interference, is comparatively rare.

*Section of the femur* has been performed, either between the trochanters, or in the neck, about its middle, and with successful results. The one line of section was originally proposed and performed by Dr. Rhea Barton, of Philadelphia, in 1826. A crucial incision was made over

the great trochanter, seven inches in length and five inches in the horizontal direction; a fine saw was introduced, the femur divided transversely between the trochanters, and the limb brought down. The result was successful; an artificial moveable joint formed: but seven years afterwards, ankylosis ensued, and two years subsequently, the man died of phthisis, nine years after the operation. A similar operation in situation—between the trochanters, but an *excision* of a transverse plate of bone, of an elliptical form upwards, by means of the chain-saw, was performed by Dr. Louis Sayre, of New York, in two cases, both in the year 1862. The object of this procedure was to form a false joint, of a ball-and-socket character. The first case was completely successful at the end of six months, the patient, aged twenty-six, being able to stand on either leg without crutch or cane; and upwards of five years afterwards the result was permanent: the man could move and walk with practical agility. In the second case, the operation was followed by abscess and necrosis; but the patient, a female aged twenty-four, died, apparently of tubercular pneumonia. Post-mortem examination showed that an artificial joint had formed; the articular surfaces were tipped with cartilage and provided with a synovial membrane, and there was a complete capsular ligament.

*Subcutaneous* section, and higher up, in the neck of the femur, was first proposed and practised, by Mr. William Adams, in December, 1869. The object of this procedure was to procure an artificial, moveable joint;

FIG. 256.

that result having failed, osseous ankylosis, but with the limb in a straight position, was sought to be established, and obtained. A long tenotomy-knife was entered a little above the great trochanter, and passed down to the neck, the capsular ligament was opened freely, and the neck of bone divided by a narrow, fine saw, applied from before backwards. (Fig. 256.) The tendons of the long head of the rectus, the adductor longus, and tensor vaginæ femoris muscles, were then divided; the limb was brought down straight, and fixed by a long interrupted Liston's splint. Five months after this operation, and subsequent treatment, the man, aged twenty-four, was exhibited at the Medical Society of London, where he walked about the room without any assistance—a successful result which has since become permanently secured. The annexed figures represent

the appearances of the limb, before and after operation; in the latter, the patient standing on the limb, to show the restored usefulness of the member. (Figs. 257, 258.)

This operative procedure has since been practised successfully in three other cases—by Mr. T. R. Jessop, of Leeds; Mr. F. W. Jowers, of Brighton; and Mr. Furneaux Jordan, of Birmingham. The fact of four consecutively-successful cases having occurred, goes so far to establish subcutaneous section of the neck of the femur as a surgical procedure for osseous ankylosis of the hip-joint with mal-position of the limb.

I may now give a summary of my own series of hip-joint cases; as

affording *typical* illustrations of the conditions of disease which are appropriate for excision, and the results, proximate and permanent, in each case; an analysis being appended, with reference to the several *questions* of importance pertaining to excision of the hip-joint for disease.

FIG. 257.

FIG. 258.

I have drawn up these cases from clinical notes carefully taken—in the first two by Mr. John B. Foster, in the second two, by Mr. Marriott, formerly House Surgeons; and in the remaining four, by Mr. T. C. Murphy, Senior House Surgeon, at the Royal Free Hospital.

**TYPICAL CASES OF HIP-JOINT EXCISION.—CASE 1.**—William M—, æt. 26. Admitted into the Royal Free Hospital, March 28th, 1864. *Scrofulous caries* of the left femur; the head and the articular cartilage entirely destroyed, the neck, great trochanter, and one inch of shaft involved, with one inch more of cancellated structure; similar disease of acetabulum, and horizontal ramus of pubes; *dislocation* on dorsum ilii with abscess; constitutional condition, *advanced hectic*; disease of traumatic origin; duration of disease, four years; treatment, three years. *Excision* of four inches of femur, and one inch of cancellated structure. *Recovery*, with a freely moveable joint and a useful limb, in three months. *Permanent* result known after two years and a half.

**CASE 2.**—John R—, æt. 16. Admitted into the Hospital, July 22nd, 1863. *Caries* of left femur; its neck and great trochanter, the head involved, with circumferential destruction of the articular cartilage, and disease in the shaft to two inches in extent, with one inch more of cancellated structure; similar disease of acetabulum; *dislocation* on dorsum ilii with abscess; constitutional condition, *advanced hectic*; immediate cause, cold; duration of disease, one year. *Excision* of four

inches and a half of femur, and the one inch of cancellated structure. *Recovery*, with a freely moveable joint, and a useful limb, in two months and a half. *Result* known to be *permanent* after five years.

CASE 3.—George C——, æt. 15. Admitted into the Hospital, June 9th, 1864. *Caries* of right femur; its head and neck entirely destroyed; great trochanter and a small piece of the shaft involved; similar disease of acetabulum; *dislocation* and abscess on dorsum ilii; *health good*; disease of traumatic origin; duration of disease, two years. *Excision* of one inch and three-quarters of femur. *Recovery*, with a freely moveable joint and a useful limb, in three months.

CASE 4.—Edward M——, æt. 8. Admitted into the Hospital, June 10th, 1864. *Caries* of left femur, its head and neck destroyed; similar disease of acetabulum; advanced hectic; immediate cause, cold; duration of disease, five years. *Excision* of two inches of femur. *Recovery*, with a moveable joint and useful limb, in two months.

CASE 5.—Jane L——, æt. 5. Admitted into the Hospital, March 4th, 1867. *Caries* of right femur, its head and neck destroyed; similar disease of acetabulum; *health good*; of traumatic origin; three years' duration, two and a half years' treatment. *Excision* below great trochanter. *Recovery*, with a moveable joint and useful limb, in four months. *Result* known to be *permanent* after three years.

CASE 6.—Catherine R——, æt. 5. Admitted into the Hospital, October 31st, 1866. *Scrofulous caries* of left femur, its head and neck destroyed; similar disease of acetabulum; *dislocation* and abscess on dorsum ilii; advanced hectic; disease apparently of traumatic origin; one year and eight months' duration, and treatment. *Excision* below great trochanter. *Recovery*, with a moveable joint and useful limb, in three months.

For the particulars of this case I am indebted to my colleague, Mr. John D. Hill, then Senior House Surgeon in the Hospital.

In two other cases, the essential particulars were similar to one or other of the above series.

ANALYSIS OF THE CASES.—The following facts respecting the foregoing cases of hip-joint disease and excision seem specially worthy of notice.

(1) *Conditions of Disease*.—*Caries* in all cases, with destruction of the femoral articular cartilage, entirely in 1, 3, 4, 5, 6, or in five cases; circumferentially only in Case 2. Extent of bone diseased was the head and neck in each case; with the great trochanter and portion of the shaft in Cases 1, 2, 3; and an extra portion of cancellated structure of the shaft in Cases 1 and 2; *caries* of the acetabulum to some extent in all cases, and of ramus of pubes in Case 1; *dislocation* on dorsum ilii in Cases 1, 2, 3, 6; or in four out of the six cases.

(2) *Immediate Cause*.—Injury in Cases 1, 3, 5, 6; cold in 2, 4.

(3) *Constitutional Condition*.—Advanced hectic in Cases 1, 2, 4, 6, or in four of the six cases; *health good* in Cases 3 and 5.

(4) *Previous Duration of Disease*.—Four years, one year, two years, five years, three years, one year and eight months. *Previous duration of treatment*.—Case 1, three years; Case 5, two and a half years; Case 6, one year and eight months.

(5) *Age and Sex*.—Age: 26, 16, 5, 8, 5, 5 years. Sex: four males and two females.

(6) *Operation*.—*Incision* T-shaped in all cases. *Portions of bone excised*: (1) Four inches of femur, and one inch of cancellated structure scooped out; (2) Four inches and a half of femur, and one inch of cancellated structure scooped out. In both these cases the medullary canal

was entered; (3) One inch and three-quarters of femur; (4) Two inches of femur; (5) Section just below great trochanter; (6) Section just below great trochanter. Small portions of the acetabulum were scooped out in each case. *Hæmorrhage* inconsiderable in all the cases. No ligatures required. Silk sutures and water-dressing applied in all the cases. No *splint* was used in any of the cases, the section of the femur being left free to form a fibrous ankylosis.

(7) Primary union ensued in all the cases, except the first, wherein the wound healed by granulation.

(8) *Results*.—Firm fibrous ankylosis, with a moveable joint and useful limb in all the cases. Period of union, average three months.

(9) Result known to be *permanent* in Case 1, after two and a half years; in Case 2, after five years; in Case 5, after three years.

ANKLE-JOINT.—The operation of excision with regard to the ankle-joint has been confusedly described in Surgical works as signifying the removal of any portion of the foot, whether pertaining to the ankle-joint or not; in the operations originated by Liston, Wakley, and Teale. But, by excision of the ankle-joint, I mean the removal of the articular surfaces of the bones which enter into the formation of this joint—namely, the lower articular ends of the tibia and fibula, and the upper portion of the astragalus.

This operation, first performed for *injury* by Hippocrates, and revived by Hey, of Leeds, in 1766, was first performed for *disease* by Moreau, senior, in 1792; then by Moreau, junior, in 1796; next by Mulder, in 1810; and probably by Champion, in 1813. But the credit of introducing the operation into British Surgery is due to Mr. Hancock, who excised the ankle-joint for disease in February, 1851. The operation has since been resorted to by Professor Humphry, of Cambridge, in four cases, and by other Surgeons, including myself.

*The Conditions of Ankle-joint Disease Appropriate for Excision*.—Disease of the ankle-joint, according to Mr. Hancock, frequently commences in the synovial membrane, and extends to the articular surfaces; thus, secondarily, involving the bones. But it may also commence, as scrofulous disease, in the cancellous tissue of the long bones—tibia and fibula, or of the astragalus, or of all three bones. In the former condition, the affected portion of the articular surfaces may be removed with safety and advantage. In the latter condition, excision is not inappropriate.

Other and different opinions are held by some Surgeons of repute, as by Mr. Furneaux Jordan, of Birmingham, both with regard to the origin of disease of the ankle-joint, and the propriety of excision. That disease rarely extends from the synovial membrane, but begins in the cancellous tissue, either of the extremities of the tibia and fibula, or in that of the astragalus; and, it is said, necessarily affects the whole of that bone. In the one condition, excision of the extremities of the long bones, as the local source of the disease, is said to be inadmissible; while, in the other condition, the whole bone—astragalus, must be excised. The former contra-indication is plainly at variance with the established practice of excision in disease of the knee-joint, under strictly analogous circumstances—when the end of the femur, or head of the tibia, is the seat of disease. Excision of the extremity of either of these long bones is not inadmissible, but only, perhaps, less favourable in scrofulous disease of the cancellous tissue.

The fair inferences from this diversity of opinion respecting the

diseased conditions of the ankle-joint for which excision is appropriate, would appear to be:—

(1) When disease commencing in the synovial membrane, has extended to and destroyed the articular surfaces of the tibia and fibula, that of the astragalus, or of both opposed surfaces.

(2) When disease, having the same articular consequences, commenced in the cancellated tissue, either of the long bones, or of the astragalus, provided it be limited to part of this bone, its upper articular portion.

(3) Whether the disease originated in the synovial membrane or in the articular cancellated tissue, resulting in destruction of the cartilages, without ankylosis; excision should be resorted to *before* the supervention of constitutional exhaustion.

*Operation.*—Hancock's description of excision of the Ankle-joint, as first performed by him in England (1851), is as follows:—"I commenced an incision behind, and about two inches above, the external malleolus, carrying it forwards beneath that process across the front of the joint, and terminating about two inches above and behind the inner malleolus. This incision included the skin, without implicating the tendons or their sheaths. The flap thus formed was dissected up, and the peronei tendons were detached from the groove behind the fibula and cut through, as were the external lateral ligaments close to the fibula, with a pair of bone-nippers. I next divided the fibula about an inch and a half above its inferior extremity, and cutting through the inferior tibio-fibular ligaments, detached the external malleolus. Turning the leg on to its outer side, I cut through the internal lateral ligament, carefully keeping the knife close to the end of the tibia, to avoid the posterior tibial artery. The tendons of the tibialis posticus and flexor communis were then detached from the groove behind the internal malleolus, and taking the foot in both hands, Mr. Avery holding the leg, I dislocated the foot outwards, thus bringing the end of the tibia with the internal malleolus prominently through the wound. These were removed by a common amputating saw, applied half an inch above the horizontal articulating surface of the tibia, the soft parts being protected by a spatula; the upper articulating surface of the astragalus was also removed by a metacarpal saw, held horizontally. The foot was then restored to its proper position, the cut surface of the astragalus being adapted to the cut surface of the tibia; and the wound having been closed by sutures, except on the outer side, left open for the free escape of discharge, the leg was placed on an external splint, having an opening corresponding to the wound."

The parts divided by this operation were—the skin, peronei tendons, internal and external, lateral and inferior tibio-fibular ligaments, and the articular surfaces of the bones. In subsequent operations, the tendons were preserved entire. In no instance have the tibial arteries, anterior or posterior, been wounded, and never has it been necessary to apply a single ligature.

*Lateral* incisions alone, without the anterior communication, have since sufficed. This was my mode of operation in two cases.

The *After-treatment* of ankle-joint excision should be conducted in accordance with the principles laid down respecting the excision of other joints; regard being had to the kind of ankylosis necessary for the use of the limb. The fixed position of the foot must be maintained during the period requisite to secure a firm ankylosis of the osseous surfaces made by excision—the lower ends of the tibia and fibula, and the upper sur-

face of the astragalus ; thus to adapt the foot for support and progression. The wounds, one on either side of the ankle, are dressed from day to day ; but the splint should be removed and reapplied *very seldom*. In my own excisions of the ankle-joint, I have fixed the leg on a flat back-splint, provided with a foot-piece ; thus secured, displacement can scarcely occur, and the side wounds are freely accessible for cleansing and dressing. Eventually, a starched bandage may be applied ; and the foot being slung from the neck, the patient gets about on crutches, as the foot is gradually brought into use.

*Results.*—Excision of the Ankle-joint, for disease, presents some most interesting results, both in relation to the mortality of this operation, and the state of the foot, with the probability of secondary amputation ; both these aspects of the operation being considered also as compared with amputation of the leg, and with Syme's and Pirogoff's operations of amputation at the Ankle-joint, severally for disease.

For certain valuable statistics bearing on these important questions, I am indebted to Mr. Hancock, who liberally placed at my disposal the manuscript of his Lectures at the Royal College of Surgeons.

(1) In relation to Mortality.—The results of 32 cases of excision of the ankle-joint for *disease* have been collected by Mr. Hancock ; all that he could find recorded in the practice of British Surgeons. Of these 32 cases, 7 died—about 1 in 5, or a fraction above 21 per cent. But of the 7 deaths, 4 are reported to have died of consumption, 1 suffering from that disease at the time of operation ; while another died of secondary syphilis. This reduces the average mortality to 1 in 16, or about 6 per cent. Of my own two cases, both lived.

#### *Author's Collection.*

(1) Charing Cross Hospital ; period, 1858-65. (Per Mr. Hancock.) Number of cases, 6 ; recoveries, 6 ; amputation after excision, 1 ; recoveries, 1.

(2) Royal Free Hospital ; period, last five years. Number of cases, 4 ; recoveries, 4 ; amputations after excision—Syme's amputation, 1 ; recoveries, 1.

(3) Chalmers Hospital, Edinburgh ; period, last six years. (Per Mr. P. H. Watson.) Number of cases, 4 ; recoveries, 4.

(4) Royal Infirmary, Edinburgh ; period, 1865-69. (Per Mr. P. H. Watson.) Number of cases, 3 ; recoveries, 2 ; deaths, 1.

(5) St. Bartholomew's Hospital ; period, 1866-70. (Per Mr. Calender.) Number of cases, 1 ; recoveries, 1.

(6) St. Thomas's Hospital ; period, 1866-70. (Per Mr. F. Churchill.) Number of cases, 1 ; deaths, 1.

(7) London Hospital ; period, last five years. (Per Mr. J. McCarthy.) Number of cases, 1 ; recoveries, 1 ; amputations after excision, 1 ; recoveries, 1.

Guy's, King's College, Westminster, St. Mary's, and Great Northern Hospitals, Liverpool Royal Infirmary, Royal Albert Hospital, Devonport, and Royal Sea-Bathing Infirmary, Margate ; period, each last five years. No cases.

*Compared with the Mortality of Amputation.*—(a) in the leg ; (b) at the ankle-joint—Syme's and Pirogoff's amputations of the foot.

(a) *Amputation of the leg*, for disease, in Civil Surgery, has a mortality of 26 per cent. ; whereas, in the results of ankle-joint excision for disease,

the mortality, already quoted, has been only 6 per cent. ; 20 per cent. difference in favour of excision

(b) *Amputation at Ankle-joint—Syme's Amputation.*—Of the *whole* number of Ankle-joint amputations—219, as collected by Mr. Hancock, in 144 amputation was performed for disease—caries. Of these, 10 only were fatal, or somewhat less than 1 in 14; and as 3 died of phthisis, 1 of diarrhœa, and 1 a year after operation, 5 deaths only remain; or a reduced mortality of 1 in 28. *Pirogoff's Amputation.*—Fifty-eight cases of this amputation represent the *whole* number, performed by British Surgeons, of which Mr. Hancock has been able to gather the particulars. Nearly 100 cases reported by Pirogoff as having been performed in Russia, are not available for statistical comparison. Of the 58 cases, 5 were fatal, or about 9 $\frac{1}{2}$  per cent. Of the remaining 53 recoveries, in 29 the operation had been resorted to for caries.

(2) *State of the Foot.*—Of the 32 cases operated on by excision of the ankle-joint, 21 recovered with good useful limbs.

*Secondary amputation, after Ankle-joint excision.*—Of the 32 cases, 2 only underwent secondary amputation, and both recovered.

*Compared with Secondary amputations, after amputations of Foot.*—(a) After Syme's operation; of the 144 cases submitted for caries, 9 underwent secondary amputation; but of these, 1 was a confirmed drunkard, 1 had been primarily operated on for traumatic gangrene, 1 two years previously for an accident, and in the remaining 2, the disease is not stated. (b) After Pirogoff's operation, of the *whole* 58 (for disease and injury) 5 only suffered secondary amputation, but in 4 of these the primary operation had been performed for caries.

Comparing these two *amputations* of the foot, Mr. Hancock observes; as regards the occurrence of suppuration, the percentage of deaths, of recoveries and periods of recovery, and secondary amputations; the evidence of British Surgery is in favour of Syme's operation, whilst as regards sloughing of the flap, it is decidedly in favour of Pirogoff's proceeding. Syme's amputation appears to be unquestionably the best for *disease*, and Pirogoff's for the accidents of civil life, since by it we preserve an increased length of limb.

**TARSAL BONES.**—Excision of the Tarsal Bones comprises certain recognised operative procedures, which correspond to the lines of the osseous articulations; as removal of the astragalus, or of the os calcis. But the plan and performance of excisional operations on the foot should not be restricted by these anatomical limitations. The modification of these operations on the foot, according to the kind and extent of the disease, well illustrates the guiding principle of excisional surgery; and this application of the general principle I have laid down, is specially advocated by Mr. Hancock, in the Lectures already referred to.

The *conditions of disease* for which excisional operations on the foot may become appropriate, are similar to those which affect other bones and their articulations; namely, the destructive results of inflammation, and especially in the form of caries. According to the extent of such disease, partial or complete excision of any one, or more, tarsal bones may be necessary. I proceed to describe the various operations, and to estimate their value by their results.

(1) *Excision of Astragalus.*—*Partial* excision of the astragalus, for disease, was first attempted by Severin in 1646, and in England by Ramsay in 1792. Since that time it has been performed by other Surgeons, but in a comparatively few authentic cases.

*Complete Excision.*—This operation, as for disease, was first performed by Mr. Busk in 1850. Three other cases only have since been recorded in England; one each by Mr. Erichsen, Mr. Holmes, and the late Mr. Statham—An incision along the outer and anterior aspect of the ankle, will expose the bone; its neck should then be severed with strong cutting pliers; and, some space having been thus made, the bone may be drawn out of its bed by the lion-forceps, the knife being used to detach its ligamentous connexions, but applied cautiously towards the inner side of the joint in proximity to the plantar arteries. It may be necessary to extirpate the bone piecemeal, when its substance breaks down in a carious state; it must then be gouged out.

Some of the *anterior tarsal bones* may have to be removed *with* the astragalus. *Liston's Operation* on the foot—as the excision thus extended, in a noted case, might be named—consisted in the removal of the astragalus, scaphoid and two cuneiform bones. The case is reported in the *Edinburgh Medical and Surgical Journal* of January, 1821.

*Results.*—Of *partial excision* of the astragalus, in 27 cases recorded; 8 were operations for disease—caries; 5 terminated well, 1 ended in ankylosis, and in 2 the result was not stated. *Complete Excision.*—In 109 cases of complete excision of the astragalus, 14 were operations for disease; 13 being for caries, and 1 for necrosis. Of the 13 cases; 1 died, 8 recovered with good and useful limbs, 2 underwent secondary amputation two years after excision, and both recovered; in 2 the results were doubtful. The case of excision for necrosis did well.

(2) *Excision of Os Calcis.*—*Partial excision* seems to have been first performed for injury, in the removal of a musket-ball from the os calcis, by Formius, as long since as the year 1669.

*Complete excision* was first performed, and for disease—necrosis, by M. Robert of Prague in 1837. The second operation, and the first in this country, was by Mr. Hancock in May, 1848. The first successful case in England was by Mr. Greenhow of Newcastle, in the same year—1848; and two equally successful cases of complete excision, in the hands of that Surgeon, followed also in that year. Since then, the operation has been practised, with varying success, by other Surgeons; principally, by Sir William Fergusson, Teale of Leeds, Humphry of Cambridge, Cann of Hereford, Pemberton of Birmingham, Potter of Newcastle, Mr. Holmes, Mr. Erichsen, and myself.

The operation is thus performed:—The patient lying on his face—with the sole of the foot uppermost; an incision, with a stout bistoury, may be commenced at the calcaneo-cuboid articulation, just above the sole of the foot, and carried backwards round the heel, forwards, to an equal point on the inner side. This *sole flap* of integument is raised forwards from the under surface of the os calcis, and in its whole thickness down to the bone, so as to form a good cushion; a slight perpendicular incision is made, opposite the tendo-Achillis, into this horizontal incision, and with a little reflection of the integument to either side, the tendon is severed from its insertion. The knife is then entered posteriorly, over the upper surface of the os calcis, and the strong interosseous ligament connecting it with the astragalus is divided, somewhat as an oyster is opened; the bone can then be raised, and its lateral attachments being cleared by a gentle application of the knife, the calcaneo-cuboid articulation is opened, and the bone completely detached.

Or, an incision may be made, as for Syme's amputation at the ankle-joint, and a *heel-flap* having been formed, the os calcis is exposed; lateral

incisions are continued, on either side, along the sole of the foot to the line of the calcaneo-cuboid articulation, whereby a short *sole-flap* is reflected forwards; and the operation completed as before. The objection to this plan of excision is the liability to sloughing of the heel-flap, in disease of the os calcis; fistulous openings frequently having formed posteriorly, where the flap is attached. The advantage of a heel-flap is that the excision can be readily converted into Syme's amputation, in the event of the astragalus being found to be extensively involved. This method, therefore, was recommended by Mr. Teale, and practised by Mr. Page, as a precautionary proceeding in excision of the os calcis.

Apart from the contingency of sloughing, I prefer the sole-flap method of excision.

(3) *Ercision of the os calcis and astragalus—Wakley's Operation*—is performed much in the same manner as the second method of excision of the os calcis alone. The only differences are; an *additional* incision between the malleoli posteriorly, curving down to the insertion of the tendo-Achillis, so as to expose the astragalus, on raising this flap of integument; and, that the integument of the heel between this incision and the incision across the heel, from malleolus to malleolus, forming the heel-flap in the other operation, is here removed. The bones are excised through the gap thus made posteriorly, by dividing the tendon and lateral ligaments; lateral incisions being continued along the foot to the line of the calcaneo-cuboid and astragalo-scapoid articulations, so as to give access to these articulations. The malleoli are removed with bone-nippers. The posterior tibial artery must be ligatured, but the anterior tibial is avoided by very cautiously using the knife, in removing the astragalus in front of the tibia.

This excision would probably meet the difficulty of disease extending up to the ankle-joint, and, in such case, prove a substitute for Syme's amputation at the ankle-joint. The operation was performed by Mr. Wakley at the Royal Free Hospital, in December 1847, and the case is reported in *The Lancet* of July, 1848.

*Results.*—Of *partial* excision of os calcis, in 42 cases, collected by Mr. Hancock, 38 were operations for *disease*; 25 for caries, 12 for necrosis with sequestra, and 1 necrosis. Of the 25, 1 died the day after operation of diarrhœa, 14 recovered at periods varying from six weeks to six months; 2 required a second operation but recovered, and 1 underwent secondary amputation; while of the remaining 7 the result is not given. Of the 12 cases; 3 recovered, 1 required a second operation, 1 secondary amputation; and of 7 the result is not stated.

*Complete Excision.*—Of 18 cases—the particulars of which are authenticated—in 14 the disease was scrofulous; and in 11 of these, this condition was entirely constitutional, in 1 it is said to have originated from a nail having been run into the heel, and in 2 to have followed sprains. Of the 11 cases; 1 died of diphtheria, 7 recovered and with perfect use of the limb, while 3 suffered secondary amputation—2 from recurrence of disease in the remaining tarsal bones, and 1 owing to erysipelas. Of the 3 cases induced by injury; 2 recovered completely, and the result of the third was doubtful.

The *general* results of complete excision of the os calcis, are thus represented in 34 authenticated cases; 1 died of diphtheria, 25 recovered completely, 4 underwent secondary amputation; and of 4 the results are not given.

In one case of excision of the *os calcis*—for caries, I removed also the cuboid bone and a small portion of the external cuneiform bone, both of which were involved in the disease. The patient recovered, and with a thoroughly sound and permanently serviceable foot; this result having been established by two years' duration, when the weight of the body could still be supported by the foot, and the ankle-joint had free motion. He walked without the aid of a crutch or stick. The particulars of this most successful case are reported in *The Lancet* of July 23, 1864.

*Compared with sub-astragaloid amputation.*—This operation has been little practised in England, but chiefly in France. It appears to have been performed altogether in 22 cases, as collected by Mr. Hancock. The results of some are not stated. Of the whole number; 6 were operated on by Malgaigne, 1 by Maisonneuve, and 1 by Nélaton; in 9 collected by Vacquer, all terminated favourably, 1 by Dr. John Traile of Arbroath, was successful; in 2 by Mr. Simon, one was successful, the other patient died of tetanus at the end of a fortnight; in 1 by Garner of Stoke-upon-Trent, the report was unfavourable, and 1 by Mr. Hancock was successful.

The *Cuboid*, *Scaphoid*, and three *Cuneiform Bones*, may severally require Excision; and preferably to removal by Chopart's amputation—in the articular line between the *os calcis* and astragalus behind and the cuboid and scaphoid in front, whereby the two latter tarsal bones, and three cuneiform bones, with the whole of the metatarsus and toes, are sacrificed. But the conditions of disease appropriate for excision rather than amputation, are not determinable by any precise rules; and either operation must be selected according to the judgment of the Surgeon in each particular case.

For the operations of excision, no particular directions can be laid down; the lines of incision must be guided by the state of the integument, and the facility for gaining access to the bone and its articulations.

The *Metatarsal Bones* may also be subjected to excision, either at their articular ends, or of the whole bones. These operations of extirpation are more desirable than the sweeping amputation of the metatarsal portion of the foot, including the toes, by Hey's operation—in the line of the tarso-metatarsal articulations. The choice of operation must, here again, be determined in each particular case, by the kind and extent of disease.

The *Toes* are not eligible for excision; except at their articulations occasionally, or of the ungual phalangeal bones. Removal of the intermediate phalanges will scarcely leave a useful toe. With regard to the *great toe*; its metatarso-phalangeal articulation may occasionally be excised, or the last phalangeal bone removed; thus preserving the ball of the toe for the support of the arch of the foot.

But the *results* of these excisions of the metatarsal bones and phalanges of the toes, or of their articulations, are less successful than in the corresponding bones of the hand; the toes or their contracted portions remaining comparatively useless or inconvenient.

**ELBOW-JOINT.**—This joint appears to be, and certainly in my own experience has been, not unfrequently amenable to treatment without operative interference, in the destructive stage of inflammatory disease, by ulceration of the articular cartilages.

The *natural cure* by ankylosis supervenes more readily, apparently, than in other joints; and fibrous union usually occurring, a moveable joint and useful limb is the result.

The following case, which came under my care, is so good an example of this mode of cure, that its history seems worthy of notice. Mrs. P—, aged forty, states (1857), that in 1840, seventeen years ago, a heavy door slamming, struck her left elbow on the outer side. Some pain and swelling ensued, which gradually subsided. Pain, however, was felt occasionally after using the arm, during the next six years. Then the forearm gradually became bent on the arm, but the limb could be forcibly straightened. In 1855, she had rheumatic fever; the injured joint was first affected with acute pain and swelling, and other joints subsequently. The swelling of the elbow proceeded to abscess, which broke and discharged matter; leaving seven sinus openings, of which, two in front, and three behind the joint, remained open for the next two years. During ten months of this period, she could not lift her arm to her head, nor feed herself with it. In 1857, the sinuses had all closed, except one which discharged slightly, a little below the head of the radius,—a not uncommon situation of opening in disease of the elbow-joint. The patient's general health remained good, at least there was no approach to exhaustion. Having regard to the quiescent state of the joint, and the satisfactory state of the constitutional condition, it appeared probable that if sufficient power of nutrition could be evoked, ankylosis would ensue. The result more than fulfilled my anticipation. After three months' treatment, by rest, strapping with the emplastrum ammoniaci cum hydrargyro, tonics and diet,—my usual course of treatment for curable joint-disease; fibrous ankylosis had taken place effectually, and there was limited motion in the joint. Improvement gradually continued, and the range of motion increased. In 1861, the patient could roll paste without pain or inconvenience; she could lift a nine-gallon barrel of beer and set it on "thrall," and she could make a bed, shaking the mattress or feather-bed without affecting the elbow. Weather, or the east wind, sometimes gave her slight rheumatic twinges in the joint. In April, 1865, the joint was neither painful nor swollen; all the sinuses had firmly and permanently closed, leaving the bony outline of the natural articulation only somewhat enlarged and irregular in shape. She could flex the forearm to an acute angle with the arm, and both pronation and supination were perfect. The action of the hand and fingers completed the perfect use of the arm.

*The Conditions of Elbow-joint Disease appropriate for Excision.*—The three conditions which severally determine the propriety of excision with regard to the joints in general, are applicable to the elbow-joint.

(1) Functional inutility of the limb, depending on disease of the joint having resulted in destruction of the articular cartilages, without the supervention of ankylosis, will always justify excision; care being taken that the constitutional condition shall *not*, if possible, have approached to exhaustion. (Fig. 259.) But the degree of reserve power requisite for recovery is much less than after excision of the knee or hip, owing to the average period of reparation being less by one-half, or about six weeks instead of three months.

(2) Osseous ankylosis, and particularly in connexion with a useless position of the limb, will also justify excision.

(3) The structural conditions of disease pertaining to the elbow-joint, which specially affect the propriety of its excision, relate to the *extent of bone* destroyed by disease. The limits of excision of the elbow-joint are not restricted by two of the three considerations respecting the knee-joint. Thus, the length of the portions of bone removed from the

elbow is comparatively unimportant; the corresponding loss of length in the arm not much impairing the use of this member eventually, nor is it of consequence, therefore, to observe the epiphyseal lines as affecting the subsequent growth of the bones. But it is equally requisite in the

FIG. 259.

elbow as in the knee to preserve sufficiently wide surfaces for the formation of an adequately secure union; in the one case, with ligamentous mobility; in the other, with osseous consolidation.

The removal of only a thin superficial section of the articular ends of the bones in the elbow-joint, leaving the section ends too nearly in contact, is apt to be followed by osseous union and an unsuccessful result of the operation. On the other hand, any new bone which may not unfrequently have been produced in the form of a spiculated enlargement of the articular ends *above* their diseased portions, and thereby limiting the disease, should not be included in the excision. (Fig. 260.) The importance of observing this limitation of the operation is particularly urged by Mr. Butcher in his work on *Operative and Conservative Surgery*.

FIG. 260.

*Operation.*—Excision of the elbow-joint, for disease, was originally performed by Justamond, of the Westminster Hospital, in 1775,—as a partial operation, in which the olecranon and two inches of the ulna were removed; complete excision was first performed by Moreau, senior, in 1794, and by Moreau, junior, in 1797; but the operation attracted little attention until it was revived by Stansfield, Chorley, and Hey of Leeds, in 1818–19; and especially by Syme in 1830; since which period it has been more generally practised than the excision of any other joint for disease.

The operation is thus performed:—a single linear incision **I**, longitudinally over the centre of the joint, and of sufficient length to turn out the bones, is preferable to any other, in relation to speedy recovery after operation. Other forms of incision offer certain special operative advan-

tages. An **H** shape exposes the bones more readily, on reflecting the flaps, thus marked out, upwards and downwards; and this incision is particularly recommended by Sir W. Fergusson. (Fig. 261.) A **—** shaped incision with the vertical line parallel to and a little outside the ulnar nerve, allows of its being more surely guarded or drawn inwards, by a curved spatula in the hands of an assistant. In either case, the transverse line of these incisions should be made across the end of the olecranon from condyle to condyle; or nearly to the inner condyle, in the latter form of incision; and thus the joint is laid open. But the single longitudinal incision is now, I believe, generally practised, and I

FIG. 261.

rarely find any other more convenient. With a little detachment of the integument on either side, the knife is entered transversely above the olecranon, dividing the tendon of the triceps,—the ulnar nerve being protected; the olecranon process must then be sawn off transversely, and by forcibly flexing the arm, and, perhaps, dividing the lateral ligaments with a light touch of the knife, the articular surfaces of the three bones are fully protruded and exposed. The articular surface of the humerus, between the condyles, is excised by means of a small saw; and the remaining sigmoid surface of the ulna and head of the radius, in like manner, or removed with pliers, or simply gouged. The latter two bones should not be excised below the insertions of the brachialis anticus and biceps muscles; for thus

the brachial artery will be protected by the intervening brachialis muscle from any fair risk of injury, in removing these portions of bone. Any surrounding *out-growth* of bone, resulting from exuberant reparative action, must not be mistaken for disease; it should not be included in the excision. The line of incision having been closed with sutures, the arm is laid semiflexed on an angular splint; or it may be placed in Mr. Christopher Heath's splint, an apparatus which combines with rest and graduated flexion or extension, graduated elongation of the limb, and entire access to the joint for dressing. To ensure the formation of flexible union, passive motion should be gradually recommenced when such reparation is established; say, in three or four weeks.

*Results of excision of Elbow-joint.*—(1) In relation to Life, or the *Mortality*.—Three *general* conclusions may be drawn from the results of one large collection of cases; those, in the Hospitals of the United Kingdom, and in the practice of individual Surgeons,—(1) a lower mortality than that of any joint-excision in the lower extremity; and in the upper extremity also, so far as statistics hitherto collected supply the data for comparison. (2) An average mortality of 1 in 8, or 12 per cent.; or even much lower, about 1 in 15, or about 7 per cent. (3) A very different mortality in the hands of individual Surgeons.

The conditions of disease, local and constitutional, in the cases selected for operation, would seem to mainly determine this difference; while, the mode of performing the operation, and the after-treatment, would also contribute to explain it.

The collection of cases, by Dr. Hodges, amounts to 119; of these, 15 died, 1 in 8, or 12 per cent.

*Author's Collection.*

(1) Royal Infirmary, Edinburgh; period, 1865-69. (Per Mr. P. H. Watson.) Number of cases, 62; recoveries, 50; deaths, 12.

(2) Liverpool Royal Infirmary; period, last five years. (Per Mr. W. J. Cleaver.) Number of cases, 30; recoveries, 29; deaths, 1; amputation after excision, 1; recoveries, 1.

(3) St. Bartholomew's Hospital; period 1866-70. (Per Mr. Calender.) Number of cases, 19; recoveries, 17; deaths, 2; amputations after excision, 2; recoveries, 1; deaths, 1.

(4) Guy's Hospital; period, 1864-69. (Per Mr. T. Bryant, from Dr. Steel, Superintendent.) Number of cases, 19; recoveries, 17; deaths, 2.

(5) Chalmers Hospital, Edinburgh; period, last six years. (Per Mr. P. H. Watson.) Number of cases, 15; recoveries, 14; deaths, 1; re-excisions, 1; recoveries, 1.

(6) London Hospital; period, last five years. (Per Mr. McCarthy.) Number of cases, 14; recoveries, 12; deaths, 2.

(7) King's College Hospital; period, last five years. (Per the House Surgeon.) Number of cases, 12; recoveries, 11; deaths, 1.

(8) Westminster Hospital; period, last five years. (Per Mr. F. Mason.) Number of cases, 12; recoveries, 12.

(9) Charing Cross Hospital; period, 1860-65. (Per Mr. Hancock.) Number of cases, 8; recoveries, 8.

(10) St. Mary's Hospital; period, last five years. (Per Mr. Gascoyen.) Number of cases, 8; recoveries, 8.

(11) Royal Free Hospital; period, last seven years. Number of cases, 7; recoveries, 6; deaths, 1.

(12) Royal Sea-Bathing Infirmary, Margate; period, last five years. (Per Mr. J. R. Clouting.) Number of cases, 6; recoveries, 6; re-excisions, 2; recoveries, 2.

(13) St. Thomas's Hospital; period, 1866-70. (Per Mr. F. Churchill.) Number of cases, 4; recoveries, 4.

(14) Royal Albert Hospital, Devonport; period, last five years. (Per Mr. W. P. Swain.) Number of cases, 2; recoveries, 2.

(15) Great Northern Hospital; period, last five years. (Per Mr. J. Willis.) Number of cases, 1; recoveries, 1.

*Compared with Mortality of Amputation of the Arm.*—By Malgaigne's statistics from the Parisian Hospitals we find; of 61 cases, for disease, 4 deaths resulting, or 6·5 per cent.;—a *lower* mortality than that after excision of the elbow-joint. But the statistical results from University College Hospital, furnished by Mr. Erichsen, show a *far higher* mortality after amputation. Of 18 cases of amputation of the *shoulder* and arm, for disease; 5 died, or 27·7 per cent.

(2) *State of the Limb.*—Of the 104 recoveries out of 119 cases, the majority (*minus* 15 amputation cases) had useful limbs, as proved by the patient being able to resume his ordinary avocations; but the details

given respecting the kind and extent of motions left are not exact. The subjoined figure represents the resulting appearance of the elbow, and arm, after excision of the joint, in a case operated on by Sir W. Fergusson. (Fig. 262.)

Fig. 262.

The *average duration* of the process of recovery cannot be gathered from recorded cases. In about three weeks generally, passive motion may be commenced, and fibrous union be completed in six weeks; a more rapid progress by half the average period requisite for *osseous* union, after excision of the corresponding joint in the lower limb—the knee.

The resulting *state of the joint*, is commonly fibrous and flexible union, rarely osseous and fixed ankylosis; the former, of course, being the result desired. In an interesting case, which Mr. Syme had the opportunity of dissecting nine years after the operation of excision of the elbow, for injury; the ulna was found united to the humerus by ligament, while the end of the radius was polished off, and played on the humerus and ulna, a material like cartilage being interposed. The ends of the bones of the forearm were locked in by two processes projecting downwards from the humerus, and strong lateral, and still stronger anterior and posterior ligaments, also bound them to the latter bone. Dissections of several cases, after successful excision of the elbow, may be found in Wagner on “Repair after Resection;” and it would seem that the general result is,—union, by more or less extensible ligament. Flexion, according to M. Robert, is composed of two movements; the forearm being first drawn up to the humerus by the triceps, and then flexed by the action of the biceps. The joint becomes nearly as useful as the original articulation. Thus, in Mr. Syme’s case, the man—a railway guard, could swing himself from one carriage to another while the train was in motion, with the injured arm, quite as easily and securely as with the other; and in one of Mr. Butcher’s cases, the man could lift a bucket of water, holding four gallons, and carry it to and fro, or lift it on to a table three feet high. Then again, the freedom of the ankylosis for the more delicate movements of the forearm and hand, was well exhibited in one of my own cases (Case 1); a milliner and dressmaker who could work with her needle readily and untiringly,—a *seven years’ permanent result of excision*.

Injury of the ulnar nerve—an occasional accident during the opera-

tion—is followed by loss of sensation in the little finger and adjoining side of the ring finger, with perhaps loss of motion and wasting of the muscles; but the sense of touch will probably return, and the other ill-consequences cease, apparently by re-union of the wounded nerve. This accident, judging from the digital paralysis, happened apparently in one of my own cases,—that of the milliner just mentioned; but the symptoms passed off entirely, as the functional use of the finger showed.

*Re-excision* may be practised, as in the knee—when necessary, rather than resort to amputation; and even a third such attempt has, it is said, been made with good results. In my table of Hospitals, 219 cases; of the 197 recoveries from the primary excision, 3 only are noted as having undergone re-excision, but with no death. Of my own 5 cases, I had to re-excise 1, and with a thoroughly successful result,—the patient resuming his occupation as a postman.

*Secondary amputation.*—Of the 104 recoveries after excision, in Hodges' collection of 119 cases, 15 of that number underwent amputation subsequently. From the collection of Hospitals, we learn; that of the 197 recoveries, 3 only were subjected to amputation, with one fatal issue.

The following cases in which I excised the elbow-joint, for disease, are here grouped together, as exhibiting the most essential particulars relating to the question of this operation; and the permanent results are also stated. The notes from which I have drawn up these abstracts were carefully taken, excepting in the first case, by Mr. T. C. Murphy, Senior House Surgeon at the Royal Free Hospital.

TYPICAL CASES OF ELBOW-JOINT EXCISION.—CASE 1.—Margaret R——, æt. 25. *Chronic synovitis*, of traumatic origin, one and a half year's duration, one year and two months' treatment. *Partial ulceration* of the articular cartilages of the humerus, ulna, and radius; with semiflexed position of the limb. *Excision.* *Recovery*, with a moveable joint and useful limb, in six weeks. *Result known to be permanent after seven years.*

For the particulars of this case I am indebted to my colleague, Mr. John D. Hill, then Senior House Surgeon in the Hospital.

CASE 2.—Thomas H. B——, æt. 29. *Chronic synovitis* of traumatic origin, one year's duration and treatment. *Ulceration* of the articular cartilages of the humerus, ulna, and radius; with semiflexed position of the limb. *Excision.* *Recovery*, with a partially moveable joint. Subsequent formation of abscess and sinuses. *Re-excision.* *Recovery*, with a moveable joint and a limb useful, in flexion, extension, pronation, and supination. *Result known to be permanent after one year and four months.*

CASE 3.—Mary M——, æt. 28. *Acute synovitis* of traumatic origin, one month's duration. *Partial ulceration* of the articular cartilages of the humerus, ulna, and radius, with subjacent caries; a semiflexed position of the limb; *excessive* and *paroxysmal pain.* *Excision.* *Recovery*, with a moveable joint by passive motion, in six weeks. *Result known to be permanent after one year.*

CASE 4.—Jane T——, æt. 31. *Scrofulous caries* of the ends of the humerus and ulna in the elbow-joint. *Ulceration* of the articular cartilages, with semiflexed position of the limb. *Excision.* *Recovery* with a partially moveable joint by passive motion, in two months. *Permanent result, at the end of six months, uncertain.*

CASE 5.—Lewis P.—, æt. 50. *Caries* of the olecranon, of idiopathic origin, ten months' duration and treatment; idiopathic abscess opposite the outer condyle of the humerus, six years previously. Carious bone gouged out of the olecranon. The joint opened in this procedure. *Excision* of the olecranon and of the end of humerus. *Recovery*, with a moveable joint.

SHOULDER-JOINT.—Disease of the shoulder-joint occurs so much less frequently than that of other joints, as to considerably restrict the opportunities for clinical observation respecting its seat of origin; the probability of natural ankylosis ensuing, or the necessity for operative interference by excision to bring about that issue. The synovial membrane, in some cases, would appear to be the seat of the disease; and then—suppuration being a rare event, fibrous ankylosis usually ensues. But caries, in other cases, is the mode of origin,—affecting the head of the humerus, less commonly the glenoid cavity, or only secondarily and partially; and then natural ankylosis rarely takes place. Caries, external to the joint, as of the coracoid process, the acromion, or spine of the scapula, must not be confounded with disease of the shoulder-joint.

Thus, may be recognised as indications for operation, the following.

*Conditions of Shoulder-joint Disease, appropriate for Excision:—*

(1) When disease, commencing either in the synovial membrane, or as caries, has extended to and destroyed the articular cartilages, of the head of the humerus, or of the glenoid cavity of the scapula, or of both surfaces; without the supervention of ankylosis. The constitutional condition should not have advanced to exhaustion; although, in even an extreme state of hectic and emaciation, recovery after excision of the shoulder-joint is more probable than after such operation on any other large joint.

Necrosis of the head of the humerus, generally necessitates excision of this portion of bone; but sometimes, in central necrosis, the sequestrum can be extracted, without excision.

Caries or necrosis of the coracoid process, or of the acromion, is, of course, a condition of disease not requiring excision of the joint.

(2) Osseous Ankylosis, a rare condition, with perhaps mal-position of the limb, would scarcely ever justify the risk of excision.

The *amount of bone* to be removed is rarely extensive; the disease being limited usually to the head of the humerus, while the glenoid cavity is comparatively seldom affected, and even then may usually be left untouched, or only scraped.

*Operation.*—Excision of the shoulder-joint, for disease, is commonly said to have been originated by Mr. Charles White, of Manchester, in April, 1768. He had previously excised the head of the humerus on the dead subject; but the operation in question consisted in removing the upper part of the humerus for necrosis, leaving the head of the bone in the glenoid cavity. Similar excisions were performed by Vigaroux, of Montpellier, in 1767, and perhaps by David, of Rouen. Ridewald, in April, 1770, appears to have first removed the head of the humerus, for arthritic disease, the patient being a man, fifty years old, in a wretched condition of health; secondary amputation was resorted to for suppuration and hæmorrhage, and death ensued. This operation was followed in the next year, 1771, by another case; Mr. James Bent, of Newcastle, excised the head of the humerus for caries, of three years' standing, and with entire success. In the same year, the operation was performed

by Leutin; then in 1778, by Mr. Daniel Orred, of Chester; and in 1786, by the elder Moreau,—a complete excision of the head of the humerus, the glenoid cavity, and a portion of the acromion; the result being successful. Mr. Syme revived the operation in 1826.

An elliptical incision, **U**, is the best form of incision, as it exposes the joint most thoroughly for examination, and facilitates the application of instruments. Sometimes a **I**, or a **7** or a **T** incision may be preferable; and, in truth, the shape of the flap must be guided by the state of the integument with regard to sinuses or otherwise. Supposing an elliptical to be selected;—A bistoury is entered

FIG. 263.

at the posterior border of the acromion and carried down with a sweep across the insertion of the deltoid, upwards to the inner border of the coracoid process. The flap, embracing the deltoid muscle, is raised by a few touches with the knife; and, by slight adduction and rotation of the arm, the head of the humerus is turned out of the glenoid cavity,—the capsular ligament having disappeared. Or, the single linear incision may be made. (Fig. 263.) An assistant protecting the soft parts with a spatula on the inner aspect of the bone, the saw is applied below the diseased portion. The head, neck, and proximate part of the shaft may be thus removed; avoiding if possible the circumflex arteries. Any carious portion of the glenoid cavity may be scraped with a gouge. As a rule, with very rare exceptions, the glenoid cavity should not be excised. The flap is replaced, and retained by sutures; and the arm, with an axillary pad, may be bound to the chest, as for fractured clavicle; or supported on a pillow, extending as a splint from the axilla. Subsequently, the forearm must be supported in a sling.

*Results of Excision of the Shoulder-joint.*—(1) In relation to Life, or the *Mortality*.—Statistics are not, at present, sufficiently comprehensive to establish more than one general conclusion respecting this question. The average mortality appears to be 1 in 5, or 6; 20 per cent., or about 16 per cent., respectively. Of 50 cases, collected by Dr. Hodges, 8 died; 1 in 6, or about 16 per cent.; and in 7 of the 8 fatal cases, the glenoid cavity had been interfered with. Of the 30 cases in the Hospital collection below, the death-rate was nearly 1 in 4, or 25 per cent.

*Author's Collection.*

(1) Royal Infirmary, Edinburgh; period, 1865–69. (Per Mr. P. H. Watson.) Number of cases, 10; recoveries, 7; deaths, 3.

(2) Liverpool Royal Infirmary; period, last five years. (Per Mr. W. J. Cleaver.) Number of cases, 7; recoveries, 6; deaths, 1.

(3) London Hospital; period, last five years. (Per Mr. J. McCarthy.) Number of cases, 3; recoveries, 1; deaths, 2.

(4) Westminster Hospital; period, last five years. (Per Mr. F. Mason.) Number of cases, 3; recoveries, 3.

(5) St. Bartholomew's Hospital; period, 1866–70. (Per Mr. Calender.) Number of cases, 2; recoveries, 1; deaths, 1.

(6) Guy's Hospital; period, 1864-69. (Per Mr. T. Bryant, from Dr. Steel, Superintendent.) Number of cases, 2; recoveries, 2.

(7) St. Thomas's Hospital; period, 1866-70. (Per Mr. F. Churchill.) Number of cases, 1; recoveries, 1.

(8) Charing Cross Hospital; period, 1865-70. (Per Mr. Hancock.) Number of cases, 1; recoveries, 1.

(9) Royal Free Hospital; period, 1865-70. Number of cases, 1; recoveries, 1.

(10) King's College Hospital; St. Mary's Hospital; Great Northern Hospital; Royal Albert Hospital, Devonport; Chalmers Hospital, Edinburgh; Royal Sea-Bathing Infirmary, Margate; period, each last five years. No cases.

(2) *State of the Limb*.—In 4 of the 50 cases, collected by Hodges, the operation was unsuccessful; leaving a balance of 46 successful cases.

The *average period of recovery*, with some use of the limb, as calculated from 31 of the cases, was four months; "a much longer period, however, than this elapsed, before the limb could be said to become really serviceable."

The resulting state of the joint, would seem to be, that the limb can never be elevated above the horizontal line, while in many cases it hangs down, without any power whatever in the deltoid, at a greater or less distance from the scapula. But the movements of flexion, extension, and adduction are usually free; abduction can often be effected to the extent of raising the arm considerably from the side; and there is generally sufficient power in the *forearm* to carry heavy weights, and perform many of the ordinary domestic tasks. The arm is, therefore, a very useful one, irrespective of the vast importance of preserving the *hand*; and thus the person is enabled to follow many of the ordinary trades.

The following cases well illustrate the successful results of shoulder-joint excision, for disease. I have abstracted the first case from careful clinical notes by Mr. T. C. Murphy.

CASE 1. John C—, æt. 21. Admitted into the Royal Free Hospital, July 30th, 1870. The patient, of naturally good constitution, had never suffered from rheumatism; but for the last two years, he had habitually drank hard. At about the commencement of that period, he was struck with a stick on the right shoulder; three months afterwards, a small abscess formed at the anterior margin of the axilla, it was opened, and has continued to discharge ever since. The arm gradually became more fixed and drawn to the side. In the course of six months, a large abscess, the size of a fist, formed under the spine of the scapula; this was opened at St. Bartholomew's Hospital. Other abscesses have since formed; so that, on admission, the shoulder presented considerable enlargement, and seven sinus-openings—three posteriorly, two externally through the deltoid muscle, and two anteriorly in the angle of the axilla. From the date of injury, up to the present time, the joint has been painless, unless the arm was forcibly moved. The general health is much reduced by the profuse and long-continued discharge. I, therefore, endeavoured to restore the patient, as far as possible, constitutionally and locally, by a sustaining diet and rest of the joint; and, as he retrogressed occasionally, from attacks of diarrhœa, I postponed interference, watching the most favourable opportunity for operation. At length, after two months and a half of this manœuvring, on October 15th, I excised the joint; performing the operation by the elliptical incision, so as to embrace and raise the deltoid muscle, thus to thoroughly expose the whole joint. The remnant head of

the humerus was sawn through below the great tuberosity; observing my usual precaution, in all joint-excisions, not to detach the vascular connexion of the surrounding integument, and making the section just level with its attachment. The glenoid cavity, denuded of cartilage, was slightly scraped and freshened with a gouge. Torsion of one or two small vessels, and one ligature, sufficed to arrest the trifling hæmorrhage. The flap being laid down, and closed by a few points of suture, no retentive splint was applied; an axillary pad, and a bandage as for fractured clavicle, kept the osseous surfaces in apposition, and the arm on the chest. The wound healed throughout by primary union, discharging only from its angles, while the sinus-openings gradually dried up. The result, at the end of about six weeks, was, a freely moveable joint, in all directions—circumduction and rotation; with power to perform these movements, but only to a limited extent that of raising the arm by abduction horizontally. The general health had so far improved; that, regaining some flesh and strength, the patient became cheerful, and said “he felt better than he had done for years.” He left his bed daily. Subsequently, however, attacks of diarrhœa recurred from time to time, and the abdomen became tumid and tympanitic; enlargement of the liver, assumed to arise from amyloid or albuminous degeneration, was diagnosed by my colleague, Dr. Cockle—under whose care the patient has since remained. He died from this organic disease, on February 4th,— $3\frac{1}{2}$  months after the operation, from which he had entirely recovered, and with a freely moveable joint. P. M. examination verified the diagnosis, and preserved the articulation, as a perfect specimen of a new ball-and-socket-joint; an entire capsular ligament has formed, and the section-end of the humerus moves freely on the glenoid cavity of the scapula—in circumduction and rotation.

CASE 2.—E—F—, æt. 17, a young lady, the daughter of a practitioner well known in this Metropolis. I was invited by him (January, 1871) to witness the result in this case, and I am thus enabled of my knowledge to speak of its perfect and permanent success; at the same time, he communicated the following important particulars to me respecting its history:—Six years ago, when this young lady was between 10 and 11 years of age, she apparently took cold, while resting on a seat in Hyde Park. Her previous health having been always good, and as she had never received any injury to the shoulder, this was the only assignable cause of what took place. The right shoulder-joint became very painful, and acute inflammation set in, followed by free suppuration in 48 hours. Dr. Sibson saw the case, and then, by his recommendation, Mr. Samuel Lane, who immediately opened the abscess. It continued to discharge copiously, for two months; so abundantly indeed, that the father, who measured with an half-ounce spoon, the quantity of matter discharged from day to day, thus calculated that the patient lost during this short period, three gallons of pus. Her constitutional condition, accordingly, was much reduced. Then—two months from the date of apparent origin—Mr. Lane excised the shoulder-joint, assisted by Mr. James Lane, and Mr. Gascoven, Mr. Pollock and the father also being present. A longitudinal incision was made on the front of the humerus, apparently at the inner border of the deltoid muscle, from opposite the coracoid process downwards to about three inches in extent, and a short transverse cut superiorly; forming a T-shaped incision. Two inches and a half of the humerus were removed, and the glenoid cavity, in a deeply carious state, was freely gouged. The patient made an uninterrupted recovery;

as reparation ensued, the appetite became voracious, and assimilation equally active. Nourishing food—meat, eggs, milk, with port wine, champagne, porter, &c., were taken eagerly at frequent intervals, by day, and even in the night. Being naturally intelligent, she declined any tonic medicine, as she felt her flesh and strength returning; her suggestive remark being,—“Which do you think will do me the most good, that which I like, or what I don't like?” The voice of Nature, thus proclaimed by Nature's child, was heeded. She made a complete recovery, and the result is—that, although the arm is four inches shorter than its fellow, she moves it freely backwards and forwards, without, however, the power to raise it horizontally, unless aided by the left hand. The motions of the forearm are perfect, so that she can work readily, write, or play the piano. The limb is, therefore, a most useful one, and this result has now been permanently established by six years' service.

**WRIST.**—Excision of the wrist comprises, properly speaking, not only the removal of the articulatory portions forming the radio-carpal articulation or wrist-joint, but also the carpus, and bases of the metacarpal bones; this extent of excision differing from that of the analogous operation on the ankle-joint, which is restricted to the removal of the articulatory portions of the tibia and fibula with that of the astragalus.

*Conditions of Wrist-disease appropriate for Excision.*—*Partial*, or *complete* disease of the wrist cannot be referred, like that of the larger and more simple joints, to an independent origin, either in the synovial membranes—three in number, or in the bones of the wrist. The lower articular end of the radius—and that of the ulna, which in relation to excision is associated with the wrist; the carpus below, consisting of eight bones, in two ranges of four in each; and the bases of the five metacarpal bones; are all so contiguous, as to obscure the precise seat of origin in caries affecting the wrist. Then again, the three synovial membranes are as one, in relation to the origin of disease in the form of

FIG. 264.

synovitis;—the membranous investment of the radio-carpal articulation, which sometimes communicates with that of the radio-ulnar articulation through a perforation in the intervening triangular fibro-cartilage; the investment between the two ranges of carpal bones, with its two prolongations upwards, and sometimes extending into the synovial membrane of the radio-carpal articulation, and the three prolongations downwards which always extend to and invest the four inner carpometacarpal articulations; and the separate synovial sac for this articulation in the thumb.

Caries of the wrist appears to be generally of scrofulous, and thence constitutional, origin—excited perhaps by some injury, of apparently trifling character, as a sprain; while synovitis seems to have another constitutional origin, probably as chronic rheumatism.

Thus, we recognise as conditions of disease for excision:—

(1) Scrofulous caries of the wrist; often involving the lower articular end of the radius, and ulna, the whole of the carpal bones, and the bases of the metacarpal bones, in a state of extensive caries. (Fig. 264.) This figure represents the wrist before excision of the lower end of the radius, in a case operated on by Mr. Hancock.

(2) Chronic synovitis, of perhaps more limited extent, but leading to caries and destruction of the articulations.

The *amount of bone* to be removed, as being apparently diseased, may vary according to the character and extent of the disease. Thus excision might include the lower ends of the radius and ulna, with the adjoining carpal bones,—in the wrist-joint; or, the bases of some or all of the metacarpal bones. But, Professor Lister insists on the complete extirpation of the wrist, in *all* cases,—from the lower ends of the radius and ulna to the bases of the five metacarpal bones, inclusive; the disease, however limited it may appear, being apt to recur in the articulatory portions left by a partial excision.

*Operation.*—Excision of the wrist was originally performed by the younger Moreau, at the close of the last century; subsequently, by a German Surgeon, Dietz, in 1839; and then again by Heyfelder of Erlangen, in 1849; but, in this country, the operation was revived by Sir William Fergusson, in August, 1851. Since that period, it has been resorted to by Mr. Simon, Mr. Erichsen, the late Mr. Stanley, and Mr. Butcher of Dublin; and practised especially by Professor Lister of Edinburgh, who has devised a particular method of operation,—for complete excision of the wrist.

*Partial excision*, consists in the removal of only one or two of the carpal bones, or other limited portions of the bones, forming the wrist. This procedure can be readily effected by slitting up any fistulous aperture leading to the carious bone, and extracting it by bone-nippers and forceps.

*Complete excision* may be performed in either of three ways. The choice of method is mainly determined by the consideration of difficulty in removing the affected bones, without dividing the extensor tendons of the fingers and thumb; the supinator tendons, radial and ulnar extensor tendons, inserted into the bases of metacarpal bones, being comparatively unimportant, in consequence of the firm fibrous ankylosis of the wrist after operation, if the result be successful.

*First method.*—A curvilinear incision is made, extending from just above the styloid process of the radius, downwards across the back of the wrist, and upwards to the same level above the styloid process of the ulna; the flap of integument is reflected, *carefully* avoiding the extensor tendons of the fingers, and those of the thumb, on the ulnar half of the radius. Then, dividing the supinator tendons, and the extensor tendons of the carpus, and flexing the wrist, the radio-carpal articulation is opened; and, while the other extensor tendons referred to are drawn aside with a curved spatula by an assistant, the articular ends of the radius and ulna, the carpal bones, and bases of the metacarpus, are successively removed by a small saw or cutting pliers introduced transversely.

*Second method.*—Two *lateral* longitudinal incisions are made, one on the ulnar, the other on the radial side, of the wrist, or on its *dorsal* aspect; thus *readily* avoiding the extensor tendons of the fingers, and that of the first joint of the thumb. The operation is then continued as before, and completed by excising the bones in the same manner.

A *single ulnar* incision is deemed sufficient by Sir W. Fergusson, and as the best mode of operation. (Fig. 265.) The resulting appearance is shown by the accompanying figure in Mr. Hancock's case. (Fig. 266.)

But Professor Lister has particularly pointed out, there are two

obvious and important objections to the lateral method, which somewhat resembles that which he has devised. Firstly, the radial incision is so placed, as probably to sacrifice the extensor tendons of the metacarpal bone, and of the second joint, of the thumb. Secondly, with regard to the

FIG. 265.

bones; that in the transverse division of the bones, an unnecessarily large amount of bone is removed from the radius and ulna and from the metacarpus,—a loss of length and breadth which interrupts the process of

FIG. 266.

consolidation, and results in a more narrow wrist and impaired strength of the hand. Moreover, that the bones being divided in the dark, some portion of the disease may probably be left behind.

To obviate these difficulties as to the excision of the bones, and to avoid the tendons requisite for the efficient use of the hand and fingers; another method of operation has been proposed and practised by Professor Lister. It consists in two essential peculiarities:—the radial incision is so placed, on the dorsal aspect of the radius, as to avoid the tendons which are otherwise liable to be implicated—the extensor ossis metacarpi pollicis, and the extensor secundi internodii; while the limited, but complete, excision of the bones is accomplished, by first removing the carpus, and then the articular ends of the radius and ulna, and the bases of the five metacarpal bones. This procedure is confessedly complicated in its detail,—“consisting of a series of operations, each one of which must be executed with scrupulous care,” and it demands accurate anatomical knowledge—an objection of no reasonable weight; the operation is also tedious to the Surgeon in its performance, and protracted for the endurance of the patient even under the influence of chloroform. These apparent objections, as to the nature of the operation itself and its performance, would, however, be entirely overruled by its more *successful* results, as compared with the simple procedures already noticed. How far *this* estimate may be in favour of the complicated method of operation, will be fairly shown by the comparative results of *both* in Mr Lister's practice.

But, in justice to a new operation, no less than to its originator, I

must first describe it; abridging the procedure as little as possible from his own description, although at the risk of proving somewhat wearisome, for all the details are urged as being found well worthy of attention.

*Third method, or Lister's operation.*—Chloroform having been administered, a tourniquet is placed upon the limb to prevent oozing of blood, which would interfere with the careful scrutiny to which the bones must be subjected. Any adhesions of the tendons are thoroughly broken down by freely moving all the articulations of the hand. The radial incision is then made. It commences above at the middle of the *dorsal* aspect of the radius, on a level with the styloid process, this being as close to the *angle* where the tendons of the *secundi internodii pollicis* and indicator meet, as it is safe to go. At first, it is directed towards the inner side of the metacarpo-phalangeal articulation of the thumb, recurring parallel to the tendon of the *extensor secundi internodii*; but, on reaching the line of the radial border of the metacarpal bone of the forefinger, it is carried downwards longitudinally for half the length of that bone, thus avoiding the radial artery which lies somewhat to the outer side. These directions will be found to serve, however much the parts may be obscured by inflammatory thickening. Next, the soft parts at the *radial* side of the incision are detached from the bones with the knife guided by the thumb-nail; so as to divide the tendon of the *extensor carpi radialis longior* at its insertion into the base of the second metacarpal bone, and raise it, along with that of the *extensor carpi radialis brevior* previously cut across, and the *extensor secundi internodii*, while the radial artery is thrust somewhat outwards. Then, the *trapezium* is detached from the rest of the carpus, by means of cutting-pliers applied in a line with the longitudinal part of the incision, but the removal of this bone is postponed until the rest of the carpus has been taken away, when it can be dissected out without much difficulty; the one procedure also not endangering the radial artery, the other having that risk. The soft parts on the *ulnar* side of the incision are dissected up from the carpus as far as may be convenient, the remainder being raised by the second or ulnar incision.

This incision, a free one, should commence at least two inches above the end of the ulna, immediately *anterior* to the bone, it is carried down between it and the *flexor carpi ulnaris*, and onwards in a straight line to the middle of the fifth metacarpal bone at its palmar aspect. The *dorsal* lip of this incision is raised, and the tendon of the *extensor carpi ulnaris* is cut at its insertion into the base of the fifth metacarpal bone, and is dissected up from its groove in the ulna, without isolating it from the integuments which would endanger its vitality. Then the extensor tendons of the fingers are readily separated from the carpus, the hand being bent back to relax them, and the *dorsal* and *internal lateral ligaments* of the wrist-joint are divided; leaving the connexions of the tendons with the radius undisturbed. The *anterior* surface of the ulna is cleared, turning the knife towards the bone to avoid the artery and nerve, the articulation of the pisiform bone is opened,—if not already done in making the incision, and the flexor tendons are separated from the carpus, the hand being depressed to relax them. To accomplish this, the process of the unciform bone must be clipped off with pliers, but the pisiform bone is left attached to the tendon of the *flexor carpi ulnaris*. In raising the tendons, the knife must not pass below the *bases* of the metacarpal bones, to avoid wounding the deep palmar arch. The *anterior ligament* of the wrist-joint is now divided. Then, introducing a pair of bone-forceps, the junction

between the carpus and the metacarpus is severed, thus completely detaching the *whole carpus*, which is extracted *en masse* with a pair of sequestrum-forceps,—leaving the trapezium and pisiform bones.

The ends of the *radius* and *ulna* are now made to protrude, from the ulnar incision, by everting the hand; and according to their state of caries on examination, the articular surfaces only, or a larger portion of the bones, should be excised. The end of the ulna may be sawn obliquely, removing the articular surface, but leaving the styloid process, and the ulna, therefore, of the same length as the radius; a provision for the subsequent symmetry and steadiness of the hand, the angular interval between the bones being filled by fresh ossific deposit. The end of the radius is then excised, by sawing off a thin slice, parallel to the general direction of the inferior articular surface. In doing this, the tendons in their grooves on the dorsal aspect of the bone need not be disturbed; it is sufficient to remove the bevelled ungrooved part of the bone-end, and thus the extensor secundi internodii pollicis may never come into view. This may seem a refinement; but the freedom with which the thumb and fingers can be extended, even within a day or two after the operation, when this point is attended to, shows its importance. The articular facet on the ulnar side of the radius is then clipped off with bone-nippers, applied longitudinally. In thus excising the ends of the ulna and radius successively, it is far better to take away too much bone than too little; a useful hand resulting in spite of very extensive excision. The *bases of the metacarpal bones* must then be examined and excised, saving as much bone as possible, but clipping off their articular surfaces transversely and laterally; even, when necessary, drilling the shaft into a hollow tube. The second and third bones are most easily reached from the radial incision, the fourth and fifth from the ulnar side. Next, the trapezium is seized with a strong pair of forceps and dissected out, carefully avoiding the tendon of the flexor carpi radialis, which lies firmly bound into the groove on the palmar aspect of this bone, and turning the knife close to the bone elsewhere to avoid wounding the radial artery. Then, having removed the trapezium, the base of the metacarpal bone of the thumb is pushed up and its articular surface clipped off; thus preventing the risk of recurrent disease, and reducing the thumb in length to the same extent as the fingers. Lastly, the pisiform bone should be examined, and its articular surface clipped off; the rest of the bone is left, if sound, as it retains the insertion of the flexor carpi ulnaris, and gives attachment to the anterior annular ligament; if unsound, the bone must be removed entirely.

In this operation, the extensors of the carpus are the only tendons necessarily divided; the flexor carpi radialis, escapes, being connected with the second metacarpal bone *below* its base, and the flexor carpi ulnaris is left attached to the pisiform bone. All the flexors and extensors of the fingers, and all the extensors of the thumb, should be uninjured, and undisturbed beyond what is absolutely necessary for the operation of excision.

On removing the tourniquet, any hæmorrhage can be readily arrested by torsion or ligature. The radial incision is closed by sutures, and also the ulnar incision at its ends, leaving the middle portion open for the introduction of lint to allow free exit of the purulent discharge which necessarily ensues.

The hand is placed on a suitable splint, extending up the forearm, and

secured by a bandage. The most convenient form is an ordinary wooden splint, with an obtuse-angled piece of thick cork, cemented to the palmar portion by means of fused gutta-percha, and with a bar of cork stuck on transversely to the under-surface of the splint so as to project at the side. Lister's splint, thus constructed (Fig. 267), possesses certain important advantages. The hand lies semiflexed, which is its natural position of repose; the fingers are midway between flexion and extension, into which it is necessary to bring them by daily passive movements; while a certain range of voluntary motion is also permitted, which the patient should be encouraged to exercise frequently during the day. Then again, this position is best adapted for allowing the extensors of the carpus to acquire

FIG. 267.

fresh attachments; and, the palm resting on the sloping surface of cork, the splint cannot slip upwards; nor downwards, secured by turns of the bandage around the transverse bar of cork. This appendage to the splint specially keeps the *thumb* in position; it is thus allowed to fall below the level of the rest of the hand, so as to be most serviceable for opposition to the fingers; while the tendency to adduction of the thumb towards the index finger is prevented by a thick pad of lint placed in the angle between the two, under the turns of bandage around the transverse bar of cork. The palmar piece of cork should be hollowed out to receive the ball of the thumb.

*After-treatment.*—Two principles must be kept in view, in order to obtain a successful result. Firstly, to procure firm ankylosis of the wrist, by retaining it in a fixed position during the process of consolidation—for a period averaging six or seven weeks. Secondly, at the same time, to maintain the flexibility of the fingers and thumb, daily; commencing flexion on the second day, whether inflammation has subsided or not. In executing these movements, each finger should be both flexed and extended to the full degree, while the connected metacarpal bone is held quite steady, so as not to disturb the wrist. Both these principles are provided for by the peculiar construction of the splint, and Professor Lister attaches more importance to their fulfilment, in the after-treatment, than to his method of operation.

Pronation and supination, also, must not long be neglected; and as the new wrist acquires firmness; flexion and extension, abduction and adduction, should be occasionally encouraged. The period during which passive motion should be practised may be resolved into this rule—it must continue until the disposition to contract adhesions finally ceases—a few weeks or a few months.

When the patient leaves his bed, and carries his arm in a sling, the weight of the hand will make it gradually droop to the ulnar side; a tendency which is best counteracted by affixing two ledges of gutta-percha

to the ulnar side of the splint—one to support the border of the hand, and the other to prevent any lateral shifting of the splint. As the hand acquires strength, more free play for the fingers should be allowed, by cutting away the splint up to the knuckles, leaving only the palm supported. Some support must be continued until the patient feels the wrist as strong without it as with it. Earlier disuse of this support would assuredly undo the work of previous management, and lead to an unsuccessful result. A year, or even two, of such finishing-off support may be required to gain the most useful hand.

*Results.*—Fifteen cases of Wrist-Excision are recorded by Mr. Lister, as having occurred in his own practice. Of these cases, 12 were successful; recovery taking place, and with a hand more or less completely useful in its varied movements of the fingers and thumb, and with combined strength and flexibility of the wrist. In 1 case the result was doubtful at the time of the report—four months after operation. In the remaining 2 cases, death ensued, though not directly from the operation; one patient dying, at the end of seven weeks, from advanced phthisis and other complaints; the other patient, after re-excision about six months subsequent to the original operation, lived yet two months longer, when death occurred from phlebitis and pyæmia. Secondary hæmorrhage, or any other bad symptom immediately referable to the operation, occurred in not a single instance.

Thus, then, Lister's elaborate method of operation has been singularly safe and successful.

Other and simple methods of operation have hitherto rarely proved successful; the results having been, in the majority of the few instances recorded, either a stiff and useless hand, or recurrence of the disease and secondary amputation.

Yet, it may fairly be doubted whether the superior results attained by Lister's method have not been due—as he himself acknowledges—more to the principles on which the *after*-treatment was conducted, than to the plan and performance of the operation. This conclusion seems to be established by two significant facts in the history of Mr. Lister's cases—that the period of recovery and the resulting condition of the hand were about equal in his earlier and later cases, while the method of operation was different.

#### *Author's Collection.*

(1) Royal Infirmary, Edinburgh; period, 1865–69. (Per Mr. P. H. Watson.) Number of cases, 12; recoveries, 9; deaths, 3.

(2) Liverpool Royal Infirmary; period, last five years. (Per Mr. W. J. Cleaver.) Number of cases, 6; recoveries, 6.

(3) Chalmers Hospital, Edinburgh; period, last six years. (Per Mr. P. H. Watson.) Number of cases, 5; recoveries, 4; deaths, 1.

(4) London Hospital; period, last five years. (Per Mr. J. McCarthy.) Number of cases, 3; recoveries, 2; deaths, 1; amputations after excision, 1; recoveries, 1.

(5) King's College Hospital; period, last five years. (Per the House-Surgeon.) Number of cases, 3; recoveries, 3.

(6) St. Thomas's Hospital; period, 1866–70. (Per Mr. F. Churchill.) Number of cases, 1; recoveries, 1.

(7) St. Bartholomew's Hospital; period, 1866–70. (Per Mr. Calender.) Number of cases, 1; deaths, 1.

(8) Royal Free Hospital; period, last five years. Number of cases, 1; recoveries, 1.

(9) Guy's Hospital; Westminster Hospital; Charing Cross Hospital; St. Mary's Hospital; Great Northern Hospital; Royal Albert Hospital, Devonport; Royal Sea-Bathing Infirmary, Margate; period, each last five years. No cases.

THE HAND may often be subjected very advantageously to various operations of Excision, both in regard to the *Metacarpal Bones*, and the *Phalangeal Bones* of the Fingers.

The conditions of Disease appropriate for Excision, are precisely analogous with respect to any such operation on these bones of the hand, as in the corresponding bones of the foot. The articular ends, or the whole, of several, or of single bones, of the metacarpus or of the fingers, may thus be removed; instead of having recourse to amputation of portions of the hand, which would unnecessarily include sound portions of this precious member. But the choice of either operation of removal, and the plan and performance of the procedure, must be determined by the kind and extent of disease, in each particular case. The general principle, here again, applies; Pathology is the guide as to the excisional operation, whereby also the portion of the hand which may be preserved, is indicated.

#### EXCISION OF THE JOINTS FOR INJURY.

EXCISION OF THE KNEE-JOINT, FOR INJURY.—The operation of knee-joint excision, for injury to the joint, can only be appropriate in certain conditions, intermediate between those which admit of cure without any operative interference, and those which should be subjected to amputation of the thigh. Such injuries are more frequently too extensive, both in regard to the joints and surrounding soft parts, to admit even of excision; and must be submitted to amputation,—which operation, therefore, for *injury*, is an alternative procedure. But the constitutional condition will very probably be far more favourable in extensive injury, than in extensive disease,—the former occurring often to persons in high health, and not when the constitutional reserve-power, necessary for the long process of reparation after excision, has been reduced by long-continued pain or exhausted by discharge and hectic fever. Hence, this primary consideration with reference to the operation, as for disease, may probably be altogether omitted in selecting excision rather than amputation for injury to the joint. The question of operation arises more commonly in Military than in Civil practice.

*Conditions of Injury Appropriate for Excision.* — (1) Lacerated Wounds of the Joint. Punctured Wound may allow of closure, and the treatment for consequent synovitis. In the event of inflammatory disease, thus of traumatic origin, having terminated in destruction of the articular cartilages, without the supervention of ankylosis; the propriety of excision must be determined by the same consideration as with reference to idiopathic disease of the joint,—namely, the measure of constitutional reserve-power. (2) Compound Fracture involving the Joint. (3) Compound Dislocation of the Joint. (4) Gun-shot wounds of the knee-joint may comprise one or more of these conditions, with perhaps the addition, as a complication, of a foreign body in, or near to, the joint.

The operation is performed in accordance with the directions already

given, when the joint is diseased; the incision being modified conformably to the state of the integument in injury of the joint.

The *after-treatment* also is the same, as to the retentive appliances, and their reapplication from time to time, only as occasion may absolutely render necessary; but the more severe inflammation apt to arise after excision for injury, must be promptly met by more actively repressive measures.

*Results.*—Cases of knee-joint excision for injury have been far less numerous than for disease; and insufficient to establish any general conclusions, as to mortality or secondary amputation.

Cases of *lacerated* wound of the joint, for which the operation has been performed, have occurred; one in the practice of Mr. Kempe, of Exeter, the patient aged thirty, and the result perfectly successful, at the end of a year the patient being enabled to load a railway van; and in another case excision was resorted to by the late Mr. Price, as a secondary operation,—the patient six years old, having two months previously sustained an extensive laceration of the knee-joint by a cart-wheel, followed by profuse suppuration and burrowing sinuses, yet apparently the result was successful.

In a case of *punctured* wound of the knee-joint, by a needle, resulting in ankylosis and dislocation; at the end of one year and four months, Sir William Fergusson excised the joint; the patient recovering with a shortened but perfectly straight limb. In a similar case, under Mr. Erichsen, the patient recovered, with the natural cure by ankylosis.

Cases of *compound fracture* of the knee-joint, for which excision was practised have occurred; Dr. Watson having performed the operation in a case of compound, comminuted fracture of the patella, the fragments being impacted in the end of the femur, and the result of its excision, fatal: Mr. Crompton, in a case of compound fracture of the condyle of the femur, had a successful result to the operation; and, in a case of forcible separation of the lower epiphysis from the shaft of the femur, the patient being aged fifteen, sloughing ensued and protrusion of the end of the femur, for which Mr. Canton excised the joint, and with a perfectly successful result. In a similar case, the same Surgeon having performed excision, re-excision of a further protrusion of the femur was practised; and fibrous ankylosis with a useless limb resulting, Mr. Canton amputated the thigh, and the patient recovered.

*Compound dislocation* of the knee-joint will rarely admit of excision; owing to the extent of disorganization, amputation may be imperative.

*Gunshot* injury to the knee-joint, has not unfrequently allowed of excision, but the results have been far more frequently successful in Civil, than in Military practice. Successful cases have occurred; one at the London Hospital, under the care of Mr. J. Hutchinson; another, at the General Hospital, Birmingham, under Mr. Crompton; and M. Spillmann has collected the history of 13 cases of knee-joint excision in Civil practice, for gunshot injury, with only 3 deaths. On the other hand, under, probably, the less favourable circumstances of Military practice, the operation has been deadly. Of 21 such cases, collected by M. Spillmann, 19 were fatal. During the Crimean War, the returns of excision show only 1 case of excision of the knee-joint, and with a fatal issue. In the American War, the report from the Surgeon-General's department, records in a tabulated form, 770 terminated cases of gunshot wounds of

the knee-joint; in 11 cases of excision, only 2 recovered, or a mortality of 90 per cent.; whilst the mortality from amputation was far lower,—73·43 per cent., still a very melancholy record. Free incisions into the joint seem to have succeeded little better than excision. The results of the operation, as collected by M. Pénier, are very impressive. In Civil practice, of 7 cases; there were 4 recoveries, and 3 deaths, or 1 in  $2\frac{1}{3}$ ; whereas, in Military practice, of 20 cases, 3 only recovered, and 17 died,—an overwhelming mortality. All these cases are taken almost exclusively from Foreign sources. It would appear, therefore, that while excision of the knee-joint for injury, may be less successful than the average *minimum* success of the operation for disease: the mortality in Military practice is so excessive, as to suggest the propriety of there abandoning the operation in favour of amputation of the thigh.

*Author's Collection.*

(1) Great Northern Hospital; period, last five years. (Per Mr. J. Willis.) Number of cases, 2; recoveries, 2.

(2) St. Thomas's Hospital; period, 1866–70. (Per Mr. F. Churchill.) Number of cases, 1; deaths, 1.

(3) Royal Free Hospital; period, last five years. Number of cases, 1; recoveries, 1.

(4) Royal Infirmary, Edinburgh; period, last five years. (Per Mr. P. H. Watson.) Number of cases, 1; deaths, 1.

(5) Chalmers Hospital, Edinburgh; period, last six years. (Per Mr. P. H. Watson.) Number of cases, 1; deaths, 1.

(6) Guy's Hospital; St. Bartholomew's Hospital; London Hospital; Westminster Hospital; St. Mary's Hospital; Charing Cross Hospital; King's College Hospital; Liverpool Royal Infirmary; Royal Albert Hospital, Devonport; Royal Sea-Bathing Infirmary, Margate; period, each last five years. No cases.

EXCISION OF THE HIP-JOINT, FOR INJURY.—This operation, like that for the knee-joint on account of injury, relates more to Military than to Civil Practice. It was first performed, as reported by Oppenheim, at the battle of Eski-Arna-Utlar, between the Russians and Turks, on the 5th May, 1829. The injury was that of a gunshot wound of the hip, with fracture of the head and neck of the femur and of the upper edge of the cotyloid cavity; the soft parts being little injured, and the nerves and large vessels untouched. Death took place after the seventeenth day, apparently, however, from fright. The operation was advocated by Guthrie; and practised during the Crimean War, both in the English and French Hospitals.

*Conditions of Injury appropriate for Excision.*—(1) Compound Fracture of the upper part of the femur, and perhaps involving the acetabulum.

(2) Compound Dislocation of the Hip-joint—a rare form of injury.

(3) Gunshot Wound of the Hip-joint; comprising either of these conditions, and more often fracture. The diagnosis, as to the kind and extent of injury may be very difficult. Possibly, no shortening, eversion, or crepitus, and little loss of power to move the limb in flexion or extension; only a small aperture to be seen in the thigh, before or behind, with no hæmorrhage, and no pain experienced by the patient.

(4) Wrench of the hip-joint, a form of injury described by Brodie, has also been suggested as an appropriate condition for excision. But,

the impossibility of an accurate diagnosis in this case, would forbid so serious an operation.

The *operation* of excision for injury is performed in the same way as for disease, modified only by the state of the integument. *After-treatment* also requires no special notice.

*Results.*—In the Crimea; of the 14 cases of this operation in the English Hospitals, only 1 recovered; of the 13 cases in the French Hospitals, all were fatal; and in the Schleswig-Holstein campaign, of the 7 cases there was only 1 recovery.

The successful Crimean case had been operated on by Dr. O'Leary. A fragment of shell struck the great trochanter of the left femur, producing a fracture, which commenced close to the head of the bone, and extended downwards and forwards between the two trochanters, terminating about an inch and a quarter below the lesser. The external wound was small. The head of the femur and the trochanters were removed. In three months the man left his bed on crutches. At the end of six months, he had gradually regained the use of his limb, and, some time afterwards, was seen in London, in excellent health.

Although an almost invariably fatal operation, the duration of life after excision shows that it has no immediate danger. In the cases recorded; one of the patients lived 5 weeks, others from 6 to 17 days, and only 1 for so short a period as 22 hours.

On the other hand, natural recovery is almost hopeless. From gunshot wound of the hip-joint, one such result occurred after the battle of Solferino; and another was seen at Nantes, in 1830, by M. Boinet.

*Compared with Amputation at the hip-joint;* in Military practice, recovery very rarely ensues, death taking place usually within a day or two after this operation.

In the dilemma from the almost certain mortality of trusting to Nature, or performing amputation; the Surgeon may perhaps judiciously have recourse to the chance afforded by excision.

In the 15 Hospitals stated in previous Tables, respecting Joint-Excisions during the last five years; it appears, from the Returns with which I have been favoured, that there has been no case of excision of the Hip-joint, for Injury.

**EXCISION OF THE ANKLE-JOINT, FOR INJURY.**—This operation is referred to by Faure, as having been performed in a case which occurred at the Battle of Fontenoy; a wound of the ankle-joint by a "biscaien." The articular ends of the tibia and fibula, with the astragalus and portions of the other tarsal bones, were excised; but amputation was performed on the 47th day. Subsequently, excision of the articular ends of bone was performed by Mr. Cooper, of Bungay, for compound dislocation; the case being referred to in 1758, by Mr. Benjamin Gooch of Norwich. Cases, in which to the extent of two, three, and even four inches, the ends of the tibia and fibula were removed for injury, are related by Bilguer in 1781. Moreau, in 1792, performed this operation, with success, for compound dislocation, 19 days after the accident. In 1805, Park alludes to a case of excision of the tibial end for similar injury to the ankle; and, according to Mr. Hey of Leeds, in the same year, Mr. Taylor of Wakefield, had performed this operation in 5 cases. Sir Astley Cooper, Liston, and Malgaigne, have advocated removal of the ends of the tibia and fibula, in cases of compound dislocation, as being preferable to reduction or amputation. Mr. Jones of Jersey, performed complete excision—the

articular ends of bone and the surface of the astragalus, as a secondary operation; 22 days after compound dislocation with fracture of the malleoli, followed by necrosis, profuse suppuration, and constitutional disturbance. In about 3 months, the patient, having for ten days previously been able to walk some distance without support, ran away from the Hospital, and walked a distance of five miles with the aid of a stick and a crutch. A similar operation for a similar condition of the parts, was performed 5 months after the injury, by C. W. Klose, in 1854. The patient, 60 years of age, at the end of 10 weeks was able to walk out with a crutch.

*Conditions of Injury appropriate for Excision.*—(1) Compound fracture of the malleoli, with perhaps contusion of the bone.

(2) Compound dislocation of the ankle-joint.

In either of these conditions, it is presumed, that the ends of bone cannot be reduced, or if reduced, kept in position; and that the integuments are not so much lacerated or contused as to slough; unaccompanied also with comminution of the other tarsal bones.

The operation, and after-treatment, require no special notice.

*Results.*—In 29 cases, reported in Jaeger's tables, only 1 death occurred. Malgaigne records the unexceptional success of 5 operations by Taylor, 6 by Josse, and 9 by Sir A. Cooper.

*Compared with amputation of the leg, for injury,* the balance is highly favourable to excision. At Guy's Hospital, the mortality has been 62·5 per cent. in primary, and 66·66 per cent. in secondary amputations; while in the Royal Infirmary of Edinburgh, Mr. Syme records a mortality of 11, or 65 per cent., out of 13 amputations for compound dislocation of the tibia and fibula.

As to the state of the foot, after excision, the resulting condition has usually been ankylosis; but in some cases, reported by Sir A. Cooper, motion was preserved.

#### *Author's Collection.*

(1) London Hospital. Number of cases, 2; recoveries, 2; secondary amputation, 1; deaths, 1.

(2) Royal Infirmary, Edinburgh. Number of cases, 2; recoveries, 1; deaths, 1.

(3) Liverpool Royal Infirmary. Number of cases, 2; recoveries, 2; secondary amputations, 1; recoveries, 1.

(4) Guy's Hospital; St. Bartholomew's Hospital; St. Thomas's Hospital; King's College Hospital; Charing Cross Hospital; St. Mary's Hospital; Westminster Hospital; Royal Free Hospital; Great Northern Hospital; Royal Albert Hospital, Devonport; Royal Sea-Bathing Infirmary, Margate; Chalmers Hospital, Edinburgh. No cases.

In each of these Hospitals, the Period is that of the last five years; and the Returns were made to me by those Surgeons whose names are severally affixed in the previous Tables.

EXCISION OF THE SHOULDER-JOINT, FOR INJURY.—The contingencies of warfare render this operation far more common in Military than in Civil practice. It would appear from the French official report in the Crimea; that in open engagements, the superior extremity was wounded once in every 4·3, and in siege operations, once in every 6·2, of all wounds reported. Of 47 gunshot wounds of the upper extremity, 28 were of the shoulder and arm. The advanced position of the soldier's shoulder,

in the act of firing, exposes that part more particularly to bullet-wounds; while it also shares the liability of other parts to grape-shot, fragments of shell, and cannon-balls.

M. Boucher of Lille, seems to have first performed the operation of shoulder-joint excision, after the Battle of Fontenoy, in May, 1745. Subsequently complete excisions were practised successfully by Percy, Sabatier, Larrey, Lauer, Ingalls of Boston, Mann, Guthrie, Baudens, Hancock, and other Surgeons.

*Conditions of Injury appropriate for Excision.*—(1) Compound and comminuted fracture of the head and neck of the humerus.

(2) Compound dislocation.

(3) Gunshot wound, involving the head or neck of the humerus; extending down the shaft even into the medullary canal. Such fissures may be left, and recovery ensue; or, the shaft to the extent of four or five inches has been removed, with the head, and a successful result ensue.

Complications, by fracture of the glenoid cavity of the scapula, through the neck, or extending into the body, or involving the coracoid and acromion processes, may require the removal of such additional fragments, or they may be left to exfoliate; the result proving successful, although recovery be protracted. Thus, Larrey's case was remarkable for the extent of bone excised,—head of humerus, acromion, and proximate end of the clavicle; yet the patient recovered, and with considerable use of the arm.

Partial excision of the head of the humerus was practised in the Crimea. The after-mobility was more restricted, than as the result of complete excision.

A bullet imbedded in the head of the humerus may not unfrequently be extracted, without excision.

The state of the integuments, and of injury to the axillary vessels and nerves, will regulate the propriety of excision.

The *operation* is performed as for disease, modified only by the state of the integuments. The shape of the incision will be chiefly directed by the situation of the wound or wounds in the skin. A shattered shoulder from gunshot wound necessitates a sort of trimming-up excision; by enlarging the wound, and extracting splinters of bone. A perpendicular linear incision, from the acromion process downwards through the middle of the deltoid muscle, will probably suffice to expose the crushed head of the humerus. Removal of the disintegrated and splintered fragments must then be performed *secundum artem*.

*After-treatment* must be conducted on the same principle.

*Results.*—In 53 primary excisions of the shoulder-joint for injury, the mortality was 16. In 34 secondary operations, there were 6 deaths. Combining these two series of cases, and adding thereto, 6 operations with 3 deaths, by Baudens, and 3 others, successful,—1 by Langenbeck, and 2 by Textor, of which it is unknown whether they were primary or secondary; the total number is 96 cases, with 25 deaths, or a mortality of 26 per cent.

*Secondary* excision has a comparatively more favourable mortality than the primary operation. Thus, in the 53 primary excisions, the percentage was 30·18; whereas, in the 34 secondary operations, the percentage was only 17·64,—a balance of 12·54 in favour of the latter. More striking are the results reported by Esmarch. Of 6 excisions of

the head of the humerus, performed within twenty-four hours after the injury, 2 died; of three during the inflammatory stage, or on the third or fourth day, 2 died; whereas of 10 after suppuration was established, only the same proportion, 2, died. Of 26 patients in the ambulances of M. Baudens; 11 immediate excisions made 10 recoveries, 3 were submitted to secondary excision, and all were successful. In the Crimean returns, also, the cases were equally successful.

The *period of recovery* after shoulder-joint excision for injury, seems to be about two or three months in respect to treatment, the complete result as to usefulness of the arm not being obtained under twelve months, or a longer period. In the Crimea, the Schleswig-Holstein campaign, and the last Indian mutiny, many of the soldiers who had been thus operated on, returned to their regiments or to a modified duty, before the end of the war.

*Compared with natural cure*, excision has proved most favourable. Thus, of 8 cases suited for excision, but which were left to nature, 5 died, and the remaining 3, at the end of six months, were uncured. Of M. Baudens' cases, 15 were left to nature; 8 of these died from purulent infection, and 4 suffered long from fistulous openings,—the remaining 3 having undergone secondary excision.

*Compared with amputation* at the shoulder-joint, the results of excision are also favourable. In the Crimea, of 60 such amputations, 19 were fatal, or a percentage of 31·6; leaving in favour of excision, a balance of 5·6 per cent.

A curious comparison has been drawn between the results of excision on the right and left shoulder-joints. According to Esmaich, operation on the right side is more successful than on the left side; of the latter cases, 6 out of 12 having died, but only 1 out of 7 of right-shoulder excisions.

#### *Author's Collection.*

(1) Royal Infirmary, Edinburgh. Number of cases, 1; recoveries, 1.

(2) Royal Infirmary, Liverpool. Number of cases, 1; recoveries, 1.

(3) St. Bartholomew's Hospital; St. Thomas's Hospital; Guy's Hospital; St. Mary's Hospital; King's College Hospital; London Hospital; Westminster Hospital; Charing Cross Hospital; Royal Free Hospital; Great Northern Hospital; Royal Albert Hospital, Devonport; Royal Sea-Bathing Infirmary, Margate; Chalmers Hospital, Edinburgh. No cases.

In each of these Hospitals, the Period is that of the last five years; and the Returns were made to me by those Surgeons whose names are severally affixed in the previous Tables.

EXCISION OF THE ELBOW-JOINT, FOR INJURY.—This operation appears to have been first performed by Wainman, of Shripton, in 1758 or 1759; the case having been one of compound dislocation, the articular end of the humerus was removed just above the olecranon fossa, the patient recovered, and with a flexible arm, "as if nothing had ever been amiss." This operation is famous in the history of Excisional Surgery of the Joints, on account of its very early date. Subsequently, Tyre of Gloucester, excised two inches and a half of the lower end of the humerus, for a compound dislocation. Larrey urged this excision upon his Surgeons, but according to Percy, without much effect; "timidity, carelessness, routine, and indifference (words to be remembered) too often

led them to prefer amputation, even under the very eyes of the old chieftain of Military Surgery." In 1840, Mr. Alcock could find no instance of the *complete* excision of the elbow-joint, in the annals of either British or French Military Surgery. It was not until the Schleswig-Holstein War of 1848-51, that this operation was really introduced into Military practice, by B. Langenbeck of Berlin, and L. Stromeyer of Erlangen. Excision of the elbow-joint for injury is, indeed, more often required in warfare than in civil practice; though the nature of the injuries, and the circumstances of the patient after operation, may, as with regard to other joints, render the prospect of recovery less favourable in the one case than in the other.

*Conditions of Injury Appropriate for Excision.*—(1) Compound and comminuted fracture of the elbow-joint. (2) Compound dislocation. (3) Gunshot-wound, involving the joint.

Fissures of the humerus, just above the joint, more commonly extend downward than upward. The track of a ball near the joint often induces caries, which would ultimately require excision.

But the state of the integument, and of the brachial artery and the nerves, at the bend of the elbow, will regulate the propriety of excision instead of amputation.

The *operation*, and *after-treatment*, are analogous to that for disease.

*Results.*—In 12 cases of severe injury to the elbow-joint, reported by Mr. Jonathan Hutchinson, the results were decidedly in favour of excision, rather than of either natural cure, or primary amputation. An elbow-joint apparently preserved by the reduction of compound fracture or dislocation, is apt to entail profuse suppuration and constitutional disturbance, perhaps necessitating amputation of the arm; or the motion and consequent use of the arm eventually is less than after excision of the ends of bone. Both these conclusions are established by Mr. Hutchinson's cases; and the latter, as to the use of the arm, is confirmed by Macleod's report of the Surgery in the Crimean War.

In *Civil Hospitals*, the success of operation is very remarkable; of 21 cases, authenticated by Dr. R. Hodges, in his excellent treatise on Joint-Excisions, a rapid recovery ensued in all but one, the fatal result of which was in no way attributable to the operation.

*Compared with Amputation*, the mortality of excision contrasts very favourably. Of 13 amputations of the upper extremity, in Guy's Hospital, on account of injury, 1 in 4·33, or 33 per cent., of primary, and 1 in 5, or 20 per cent., of secondary operations, proved fatal.

In *Military Hospitals*, the results have been less successful, but still in favour of excision. Combining the experience of the Crimean War, and of the Schleswig-Holstein campaign, we have a total number of cases in proof of this position. Of 60 excisions, 11 were fatal, or a mortality of 18·33 per cent. Whereas, of 208 *amputations*, 48 were fatal, or a mortality of 23·07 per cent. Thence, a percentage of 4·74 in favour of excision. *Partial* excisions have not been so successful as the complete operation. This was shown in *civil* practice, by the results of 7 of the 21 cases referred to, where the partial operation was performed; 3 made good results, 1 ended in partial ankylosis, in 1 extension was imperfect, in 1, failure was imputed to habits of intemperance, and of 1 the result is wanting. *Military* practice, as taught by the results of the Crimean War, points to the same conclusion. Partial excisions of the elbow were more tedious in recovery, more liable to fail, and the results, when successful, were less perfect.

*Secondary* excision, at the period of suppuration, say at the end of a week, if it be not preferable to the primary operation, would seem not to be unfavourable to recovery. This is the opinion of Stromeyer, and it is confirmed by Esmarch's statistics—that of 11 excisions within the first twenty-four hours of the injury, 1 died; of 20 performed during the inflammatory stage—from the second to the fourth day, 4 died; of 9 secondary excisions in the period from the eighth to the thirty-seventh day, only 1 died.

The *right* elbow-joint, like the right shoulder, would appear to be more favourable for excision, in regard to recovery. On the right side, only 2 in 20 operations proved fatal; whereas, on the left side, 4 in 19 were fatal—a more than double mortality. Indeed, comparing the total results of the shoulder and elbow-joint excisions, the mortality on the left arm to that on the right is as 3 to 1.

In each of these Hospitals, the Period is that of the last five years; and the Returns were made to me by those Surgeons whose names are severally affixed in the previous Tables.

EXCISION OF THE WRIST, FOR INJURY.—A partial excision of the wrist-joint—the radio-carpal articulation, appears to have been first performed, for injury, by Cooper of Bungay. “He sawed off the head of the radius, which passed through and made a dismal laceration of the tendons at the wrist, and the patient found little or no defect in the strength or motion of the joint.” Thus reported by Benjamin Gooch, in 1758, this operation was practised also by that Surgeon, who succeeded beyond his expectation in cases of a similar nature. At about the same period, M. Bagieu removed the comminuted bones of the wrist-joint, crushed by gun-shot injury; ankylosis ensued, and the fingers were left so flexible, that the patient, a soldier, aged twenty-five, was able to write and draw, and retained to a very considerable extent, the shape of the hand. About the year 1773, Bilguer excised some two or three inches of the wrist-end of the ulna, in a case of injury. In 1800, M. St. Hilaire of Montpellier, removed the ends of both radius and ulna, for compound dislocation, and with perfect success. In 1828, M. Hublier of Provins, performed the same operation, for similar injury accompanied with rupture of the tendons; and Huguier and Rossi repeated it for gunshot wounds of the wrist. Subsequently, excision was performed in the Crimea.

*Conditions of Injury Appropriate for Excision.*—The comparatively few cases recorded, with regard to excision for injury, are insufficient to establish any general conclusions. But, so far as experience has extended, and the analogy suggested by other joints, the following forms of injury to the wrist would seem to be proper for some such operation.

- (1) Compound and comminuted fracture.
- (2) Compound dislocation.
- (3) Gunshot wound, comprising either or both these conditions.

The complication of injury to the tendons at the wrist, does not forbid the operation; but the state of the adjacent vessels and nerves may be more important. Preservation of the hand, even in the most imperfect result for use, is so great a gain over the entire loss of this member, that the chance offered by excision will generally be preferable to primary amputation, at the wrist or in the forearm.

The *operation* and *after-treatment*, must be conducted on the principles laid down as for disease, modified only by the circumstances of the injury.

*Results.*—Some of the earlier cases have already been noticed. In the Crimea 3 cases of wrist-injury were submitted to excision, with 1 fatal result.

*Partial excision*, for compound dislocation of one or more of the carpal bones, has been practised occasionally, and with some success. Thus, Sir A. Cooper removed the scaphoid, and Malgaigne, the semi-lunar bone.

#### *Author's Collection.*

(1) London Hospital. Number of cases, 1; recoveries, 1; secondary amputations, 1; recoveries, 1.

(2) Royal Infirmary, Edinburgh. Number of cases, 1; deaths, 1.

(3) St. Thomas's Hospital; Guy's Hospital; St. Bartholomew's Hospital; King's College Hospital; St. Mary's Hospital; Westminster Hospital; Charing Cross Hospital; Royal Free Hospital; Great Northern Hospital; Liverpool Royal Infirmary; Royal Albert Hospital, Devonport; Royal Sea-Bathing Infirmary, Margate; Chalmers Hospital, Edinburgh. No cases.

In each of these Hospitals, the Period is that of the last five years; and the Returns were made to me by those Surgeons whose names are severally affixed in the previous Tables.

#### EXCISION OF BONES.

EXCISION OF UPPER JAW and LOWER JAW.—See DISEASES of the JAWS, Ch. XLIV.

EXCISION OF THE SCAPULA.—Complete Excision of this bone was originally performed by Cumming in 1808; afterwards by Gaetani Bey, 1830; and by Larrey, 1838; each of whom amputated the arm, and then excised the scapula; and more recently by Syme, Jones of Jersey, Cock, Fergusson, and Pollock, all of whom disarticulated at the shoulder-joint, leaving the arm untouched. The scapula, with the clavicle, have been removed by American Surgeons; by Massey, 1837; by McClellan, 1838; and both these bones, or rather the outer half of the clavicle, with the upper extremity, have been removed by Gilbert, in two cases; and by Massey, 1845. Partial excision of the scapula has been practised by Liston, 1819; Luke, 1828; and by Hayman, Janson, Wützer, Textor, Gross, and the Author. In these operations, the glenoid cavity was always left,—the only portion in Gross's case.

The *conditions of disease* for which excision of the scapula may be required, in whole, or in part; are caries or necrosis, and tumour.

The *results* of operation have been successful in the majority of cases,

unless from the recurrence of the disease, and the arm has become very useful. Even the formidable operations of excision including the clavicle, and with amputation of the upper extremity, have proved successful.

*Operation.*—*Partial* excision of the scapula, for caries or a tumour, will require an incision, varying in shape and extent, according to the portion of bone, or the size and relative position of the tumour, to be removed; thus, the *body* of the scapula may be excised by a **T**-shaped incision, so placed as to correspond to the spine and middle of the body of the bone. The flaps having been well reflected, and the bone or tumour thoroughly exposed, the saw is applied below the spine and the neck of the bone, which is then dissected out of its bed. Hæmorrhage may be considerable, unless the subscapular or the dorsal artery be divided. The *spine* of the scapula may be readily exposed by an incision along its projecting border from the acromion, or to include this process if necessary. The bone is removed by a small saw or cutting-pliers, care being taken to avoid the joint, if the acromion be removed. Hæmorrhage will probably be considerable, no vessel of any consequence having been severed. I have thus removed this portion of the scapula with little difficulty. The *supraspinous* portion of the bone might be reached by a similar procedure.

*Complete* excision of the scapula may be accomplished by a similar operation to that for the removal of the body of the bone. A **T**-shaped incision, but extending from the acromial end of the clavicle to the posterior border, and vertically downwards to the inferior angle, of the scapula. The flaps, thus marked out, are to be well reflected; then, the acromio-clavicular articulation must be divided, or the adjoining portion of the clavicle or the base of the acromion may be sawn through, the muscles attached to the coracoid process must be divided, and the shoulder-joint opened, carefully avoiding the axillary artery and plexus of nerves on its inner aspect; lastly, the muscles attached to the superior and posterior borders of the bone are divided, with the supra-scapular and dorsal arteries, and the bone raised from behind forwards to the axilla, there dividing the subscapular artery in completing the severation of the axillary attachments. Or, the bone may be raised from the axilla backwards, dividing the subscapular artery in the first instance; a less convenient method of procedure, owing to the copious hæmorrhage. The vessels must be secured by ligature or torsion; and the amount of hæmorrhage may be perilous, in proportion to the vascular character of the tumour. The flaps of integument are replaced and retained by points of suture.

The resulting appearance after this operation, in a case by Jones of Jersey, is here shown (Fig. 268); and the usefulness of the arm is

FIG. 268.

represented by the result of another complete excision of the scapula, by Mr. Syme. (Fig. 269.)

FIG. 269.

EXCISION OF SCAPULA, WITH AMPUTATION OF THE ARM AT SHOULDER-JOINT. — This formidable operation was originally performed, as already stated, by Cumming, 1808, and afterwards by Gaetani Bey, 1830, and by Larrey, 1838; all of whom operated for gunshot injury,—involving the arm, shoulder-joint, and scapula. A similar operation, for injury from machinery, is recorded by Mr. Patrick Heron Watson in the *Edin. Med. Journ.*, 1869. But this double operation,—excision and amputation, has also been performed *separately*, an interval of time elapsing between the former and the latter. Thus, Rigaud of Strasbourg, removed the scapula and also the outer extremity of the clavicle, eight months after amputation at the shoulder-joint. In two months the wound healed, and two years afterwards the patient still remained well. A similar operation was performed by Sir W. Fergusson in 1847, for

caries of the scapula; amputation of the arm at the shoulder having been performed three years previously, for similar disease. In the adjoining representations (Figs. 270, 271); one shows the lines of incision in the shoulder-stump; and the other the appearance of the shoulder, without the scapula, in 1864, or seventeen years after operation. The patient was still alive and well in 1870, twenty-three years after operation.

EXCISION OF THE CLAVICLE. — *Partial* excision of this bone, for necrosis, may be accomplished by an incision along the affected portion of bone, which lying subcutaneously, can be removed with tolerable facility. The sternal end of the clavicle has been excised on account of its pressing on the œsophagus, in a case of permanent dislocation backwards.

*Complete* excision of the clavicle, for an osseous tumour, may be undertaken in like manner, by an incision extending along the bone from end to end; but owing to the subjacent parts, the removal of the entire bone is a proportionately more formidable operation.

This bone has been wholly or partially excised by Mott of New York, 1828; Warren, Travers, Davie of Bungay, Curtis of Chicago, Cooper of San Francisco, and Syme.

EXCISION OF THE RADIUS OR ULNA. — The bones of the forearm have each been subjected to excision, *partially* or *completely*. Thus, Dr. Butts of Virginia, and Mr. Erichsen, have removed the whole *radius*; in the latter case, the articular head of the bone, being sound, it was left. The

result was a useful arm. Carnochan of New York, and the late Mr. Jones of Jersey, excised the whole *ulna*, successfully. Sir William Fergusson

FIG. 270.

FIG. 271.

has also performed these excisional operations, and with entirely successful results, in the preservation of a useful arm. (Figs. 272 and 273.)

FIG. 272.

The one figure represents the appearance of the arm, after excision of the radius,—showing the cicatrix-line of incision along the place of the

FIG. 273.

radius; the other figure, a similar representation, of the cicatrix-line of

incision along the place of the ulna. Cases such as these were among those originally selected, by Sir W. Fergusson, in illustration of Conservative Surgery.\* But as exhibiting the guidance of the conditions of *disease*, in the design and performance of excisional operations on the joints, and bones; the term Pathological Operative Surgery, which some years since I suggested,† would seem to be more appropriate than that of Conservative,—which merely expresses the obviously implied object of all Surgery. The *guiding* principle referred to is far more important and significant; for Surgery must, necessarily, be conservative or preservative,—or, it is nothing. As representing the *Operative* character of this aspect of modern Surgery, in regard to the joints and bones; I have also designated it, simply, Excisional Surgery.

EXCISION OF THE TIBIA OR FIBULA.—*Partial* excision of either of these bones, in consequence of disease or injury, can be accomplished without much difficulty by simple incisions, varying according to the circumstances of the case.

*Complete* removal of the fibula was readily and successfully performed by Erichsen, for necrosis, in a child six years of age; the line of incision corresponding to the whole length of the bone. After such operation, an inner splint must be applied to obviate the tendency to varus which will ensue.

## CHAPTER XXXVIII.

### AMPUTATIONS.

GENERAL DIRECTIONS.—Amputation is the removal of any part of the body by a cutting operation of severation. This kind of operation relates chiefly to the Limbs. It may be practised for Injury or Disease; but amputation is performed in a *sound* part, more or less remote from the seat of the morbid condition; Pathology only *negatively* guiding the operation in the selection of that part, yet thereby materially affecting the result. [P. p. 832.]

The conditions of Injury or Disease, which necessitate Amputation, I have already considered in previous Chapters—especially with reference to Contused Wounds, Compound Fractures and Dislocations; it remains only to here describe the operations themselves—the how to do them.

Certain directions are common to all Amputations.

*Instruments.*—Few and of simple construction, amputating instruments and appliances comprise;—a tourniquet (Fig. 274) for preventing hæmorrhage by compression of the main artery, amputating knives of various lengths and shapes (see Figs. 275, 287), a saw (see Fig. 246), and cutting-pliers (see Fig. 152), the latter for removal of any spiculæ of bone; artery-forceps (see Fig. 39) or tenaculum, for seizing or hooking arterial vessels, ligatures (see Fig. 39) or acupressure-needles and wire (see Fig. 40) for tying or compressing them, suture-needles and silk or wire (see Fig. 31); strips of diachylon or isinglass plaster, and roller bandages, sponges and lint, with a supply of cold water, are of course included among the requisite surgical appliances. A few minutes' personal examination of these

\* Med. Times and Gaz., January, 1852.

† Med. Times and Gaz., August and July, 1865.

instruments will enable the youngest student to understand them far better than by any lengthened description. Some of the instruments are not absolutely necessary, or comparatively seldom requisite. A tourniquet may be dispensed with, provided pressure be made on the main artery by the thumb of a steady assistant. The advantages of a tourniquet are, that it compresses the smaller arterial vessels as well as the main trunk—the band portion encircling the limb, and that the compression of the pad is uniform and unfailing; the disadvantage is, that it also arrests the venous circulation, thus causing a greater loss of venous blood. This may be avoided by not screwing up the instrument tightly until just before commencing the operation. Cutting-pliers will not be required unless the bone be allowed to snap by dropping the distal portion of the limb, before the saw has passed completely through the bone. A tenaculum can be needed only where the artery must be “dipped” for; as an interosseous artery in the angle of two bones, just below the knee or elbow-joint, in amputations of the leg or forearm at these parts. Ligatures may be set aside if acupressure-needles be used; and possibly both dispensed with, by torsion of the vessels.

The instruments should be arranged on a small table or tray close at hand to the operator, or the assistant handing them to him; and he should *himself* see that everything is prepared before he begins the operation. This injunction applies equally to all Surgical Operations.

Assistants are required, varying in number according to the magnitude of the amputation; one assistant specially to administer chloroform, another to command the artery, a third to retract the flaps, and a fourth to support the limb, and, after its removal, to apply the ligatures as the arteries are seized by the operator. Thus the operation will be conducted in an orderly manner. In an emergency, fewer assistants will suffice, if they be instructed to do double duty.

*Operation of Amputation.*—Two forms of Amputation are practised; flap amputation by transfixion and cutting two flaps outwards, or one inwards and the other outwards, as regards the passage of the knife; circular amputation, by cutting from the skin towards the bone by a circular sweep of the knife, successively applied, with retraction of the divided integuments, or by two oval semicircular sweeps, progressing in like manner towards the bone. A combination of these two methods is sometimes practised; as by a single long flap on one aspect of the limb, and a transverse incision on the other side—Teale's amputation, or amputation by a long and a short *rectangular* flap.

The *flap* amputation will be described so thoroughly in particular amputations, as of the thigh, that it would be superfluous to introduce it here.

The *circular* amputation may be conveniently noticed once for all.

FIG. 274.

The preliminary arrangements having been made as for a flap amputation, the Surgeon stands in the relative position necessary to grasp the thigh, for example, with his left hand just below the part where he is about to amputate; the integuments must then be drawn up by an assistant who grasps the limb with both hands. Holding the knife lightly, but securely, the operator passes it under the thigh, bending his hand back until the edge of the knife lies on the inner and anterior surface of the thigh. (Fig. 275.) Sinking the edge through the *skin*, he carries it deliberately round under the limb, and then over it, gradually changing the bend of the wrist, until the hand is as much inclined forwards as it was in the opposite direction; and thus completes a circular incision. Whatever be

FIG. 275.

the extent of retraction produced, the integuments should still be drawn upwards, evenly around the limb; the knife is again applied as before, at the line of retracted integuments (Fig. 276), and made to sweep round the limb, passing half an inch or more through *aponeurosis* and superficial muscular fibres. The assistant, continuing to draw upwards, presents a fresh surface high up, and passes his hand down into the wound to secure the surface already gained; a third time, the knife is made to encircle the limb, at the upward line of the second incision, dividing the *muscles*, large blood-vessels and nerves, down to the bone. Retraction being continued by the assistant, some muscular fibres may be made to appear, attached to the bone for an inch or more above the line where the knife first touched the periosteum; these are divided with the point of the knife. The saw must then be applied at the highest part where the bone is thus exposed, and the bone sawn across transversely; the saw being worked freely from point to heel and not fiddled irregularly. In making retraction deep towards the bone, it will generally be requisite or advantageous to employ a retractor—a broad piece of linen with a longitudinal slit in it; this appliance proving more efficient than the fingers. In practising circular amputation on the dead subject, the flaccid state of the muscles, as contrasted with their

tonicity during life, even under the influence of chloroform, will render it unnecessary to employ a retractor or to use the more forcible manual retraction, above directed ; but this difference only affords another illus-

FIG. 276.

tration of the general distinction between operations on the dead and the living. [P. p. 834.]

On allowing the integuments and muscles to fall down and regain their position ; a conical cavity is formed, sloping gradually from the circular line in the skin, as the base, up to the bone, as the apex of the cone ; presenting a loose but fleshy stump. The vessels are secured, and the integuments adjusted by sutures, as in the flap amputation.

The *relative merits* of these two methods of amputation have been much discussed ; and some Surgeons have practised almost exclusively the one, and some, the other operation. Mr. Liston advocated flap amputation, and Sir W. Fergusson seems to prefer it, although fully acknowledging the good results of circular amputation in the hands of many excellent Surgeons. I am a disciple of the former distinguished Surgeon, originally as my teacher ; and having performed the flap amputation almost invariably, for many years, with ease and the production of permanently good stumps, I am inclined to recommend its general adoption. These two methods of amputation may perhaps be thus estimated ;—flap amputation is decidedly more easy of execution ; circular amputation has sometimes the advantage of a more successful result in a good stump. Both, however, may prove equally satisfactory in this respect, with care during the operation, in the formation of the stump, and in the subsequent dressing. Flap amputation is decidedly superior at any joint ; and circular amputation in the continuity of a bone, when the limb is unusually fleshy. I have sometimes overcome the difficulty of redundant flaps, by passing the knife above and below the bone, in making the flaps, so as to leave a wedge-shaped portion, and thus reduce their bulk.

*Amputation by a Long and a Short Rectangular Flap—Teale's Operation.*—The object of this method of amputation is twofold—to procure a more useful stump, and to diminish the mortality of the operation. Accordingly, the long flap is formed from that side of the limb which does not contain the principal blood-vessels and nerves, and is made long enough to fold easily over the end of the bone, its length and breadth being equal to half the circumference of the limb; while the short flap is one-fourth its length, and contains the vessels and nerves divided transversely. No dressing is used, and the stump should not be lifted for many days.

*Carden's Amputation at the Knee-Joint* is designed on the same prin-

FIG. 277.

ciple, the incisions (Fig. 277) being similar, and the stump as here represented. (Fig. 278).

The alleged advantages of this method are, the prevention of tension by the ample size of the long flap; that, folding over the end of the bone, the flap soon acquires organic union therewith, and closes up the exposed veins; that, the limb remaining undisturbed by lifting and dressing, early closure of the veins is thus also favoured; that the end of the bone is covered by a flap free from large nerves and blood-vessels, and that the cicatrix does not adhere to it. The disadvantages

FIG. 278.

are, the necessity of sawing the bone at a higher point when one long flap only is made, than when two shorter ones of more equal length are fashioned—thus violating the established rule of not removing a limb at a higher point than is absolutely necessary, and impairing also the utility of the stump whenever its length may be a consideration of consequence. In

many injuries, with much damage to the soft parts, the operation would be impracticable, and the increased danger of a higher amputation would have to be encountered. In malignant or other recurring disease, the risk of recurrence in the long flap would be far greater than in two shorter ones, the bone being sawn at the same level. If primary union fail, the bulging of the large anterior flap will be more unmanageable than that of two smaller flaps.

*Dressing of a Stump.*—The general plan of putting up a stump, and after-dressing, is as follows:—Supposing, for example, it be a stump of the thigh, the flaps or wound should be well cleansed of any blood or chance foreign matter, by gently sluicing the surfaces with cold water

squeezed from a sponge, a basin catching the streams underneath the stump. Or, a weak solution of carbolic acid may be used, in like manner, as an antiseptic. The surfaces must then be adjusted, so that the edges lie evenly and easily in contact when brought together. Any ligatures, or acupressure wires, when they are used, should be drawn out at the nearest angle of the wound, and gently held under the finger of the assistant in charge of the flaps. Sutures or stitches are employed to retain the edges in apposition. Commencing most advantageously, for equal shaping of the stump, by introducing the first suture-needle in the middle of the stump, it should transfix either lip at about half an inch from the margin, so as to bring together a sufficient thickness of integument to support the flaps and induce primary adhesion. The thread is drawn through, and tied, without slipping, in a double knot, and the ends snipped off close to the wound. Other sutures are introduced in like manner, on either side of the first; and as many as may be necessary—no more, to keep the flaps together throughout the line of union. At one or both angles of the wound, as may be convenient, the ligatures having been collected, are protected from disturbance by a small strip of plaster overlaying them. Strips of adhesive plaster are drawn around the end of the stump, in the intervals of the sutures, thus further supporting the flaps and favouring adhesion. A strip of lint, soaked in water, or smeared with spermaceti ointment, or carbolic oil, is laid along the whole length of the wound, and a roller applied so as to encase the stump, but with a very moderate degree of pressure. Sometimes, a hæmorrhagic tendency is evinced by oozing of blood; the roller should then be applied more tightly for a time, or a compress of lint above and below the flaps may be advisable as an additional support and security, in putting up the stump.

On placing the patient recumbent in bed, the stump should be elevated on a pillow, and, no hæmorrhage supervening, it should be left undisturbed for some days—two, four, or six days, according to the degree of tension, the appearance of discharge, and atmospheric conditions as to temperature, or otherwise. Meanwhile, any liability to disturbance by spasmodic jerking of the limb may be controlled by a roller turned once round the stump and secured to either side of the bed. Opiates may also be administered, if necessary, for this purpose, and to procure sleep.

*Re-dressing* the stump must be done gently; the roller slit up with scissors, and the strips of plaster removed and replaced one by one, leaving those that still retain a good hold, and probably all the sutures. Care must be taken not to disturb the ligatures. A fresh strip of lint dipped in water—water-dressing, is reapplied, or a solution of carbolic acid, as an antiseptic, and over all, the support of a roller, lightly and evenly applied, will still be requisite. Subsequent dressings may be reduced and made yet lighter, their re-application having regard especially to the counteraction of any tendency to *bagging* by the collection of matter. Ligatures should be removed as they loosen from time to time; or acupressure-needles may be withdrawn in three or four days after amputation.

Any modifications of these proceedings, or further details, will be suggested by a general knowledge of the management of Wounds.

*Morbid Conditions of, or affecting, the Stump.*—(1) *Secondary Hæmorrhage.*—Hæmorrhage is named secondary when it occurs after an interval of a few hours, more or less, subsequent to an injury. It may arise from local or constitutional causes. *Local* causes comprise misapplication of a

ligature, as when, not having been applied transversely, or when, having included some surrounding texture, it shifts its position or loosens; a collateral branch just above the ligature may be the source of hæmorrhage, if wounded, or lead to hæmorrhage from the ligatured vessel by disturbing the formation of a clot; in the one case, hæmorrhage occurs soon after ligature; in the other when it separates; a diseased state of the coats of the artery ligatured is also followed by hæmorrhage. *Constitutional* causes include reaction after the stump has been put up, many vessels not bleeding at the time the main trunk was ligatured, and even this vessel will not bleed in a state of great collapse; excessive reaction has the same effect; an aplastic state of the blood will delay and impair the formation of clot within the vessel; and blood-poisons also have this effect, or by inducing erysipelas or sloughing of the wound, the result is the same—secondary hæmorrhage.

The *phenomena* of such hæmorrhage are not, as with primary arterial hæmorrhage, a jetting stream of florid blood; but, after a while, the blood wells up from the wound, and oozes through the dressings, then ceasing perhaps, it recurs again in a few hours. A stump should, therefore, always be watched for some time after amputation; and in the event of blood oozing, its continuance should be tested by sponging the part dry and overlaying it with a piece of dry lint, so as to detect any further escape. The *period* when secondary hæmorrhage occurs is variable; separation of the ligature is always a time for vigilance.

*Treatment* must have reference to the presumed cause of hæmorrhage, as mainly determined by the period of its occurrence. *Early* secondary hæmorrhage—within a few hours or days, may generally be suppressed by elevating the stump, and the application of cold and pressure to the flaps, a compress above and below being used and the bandage tightened. This failing, the stump must be opened up, the vessels sought for and tied, and the flaps replaced when the bleeding is controlled. *Later* secondary hæmorrhage—after ten days or a fortnight, proceeds more probably from the main artery in the stump; a ring tourniquet applied to that vessel above the stump will perhaps arrest the bleeding: this failing, the stump may be opened up, the coagula turned out, and the vessel sought and tied; or a ligature applied to the vessel above the stump. The choice between these two latter proceedings should be determined by the state of the stump—not as regards the soundness, but the unsoundness of the union. In the one case the vessel should be sought *in situ*, in the other, *above* the stump. Ligature *high up*, as by the Hunterian operation, may even thus be requisite. In the event of any failure in arresting the hæmorrhage, these different proceedings should be had recourse to *successively*.

(2) *Necrosis*.—Death of the end of the bone, and a resulting sequestrum or exfoliation may occur; either from injury to the bone by rough use of the saw; or in consequence of suppuration, sloughing, and exposure of the bone. The dead portion must be removed, when loosened.

(3) *Conical Stump*, with protrusion of the bone.—This morbid condition arises; either from insufficient coverings of the bone, at the time of amputation; or from spasmodic retraction of the muscles, subsequently. In either way, the bone protrudes, and the stump has, or acquires, a conical shape upwards from the bone as its *apex*. Sometimes, the bone threatens to protrude under a thin ulcerative cicatrix, which is unable to bear the slightest pressure or motion.

The protruding or projecting portion of bone must be excised, and the stump re-fashioned. An incision on the side opposite to the vessels should fairly expose the bone, which is then sawn off, and the flaps readjusted. In an extreme case, amputation of the stump must be resorted to.

(4) *Neuralgia* of the stump may arise from local or constitutional causes. Commonly, it arises from a more than usually bulbous enlargement of the ends of the nerves in the stump, or from adhesion to the cicatrix. Excision of any such enlargement will be necessary, or subcutaneous division of the cicatrix will be appropriate in the latter case. Excision of the end of the bone may be requisite, to relieve pressure and tightness arising from that cause. In a case of painful cicatrix after Chopart's operation; I divided the cicatrix subcutaneously without much effect; but at a later period, I removed the subjacent portion of the astragalus, with a perfectly successful result. The tendo-Achillis had been divided, to overcome retraction of the stump and tilting forwards of the astragalus under the cicatrix. An hysterical constitutional condition not unfrequently causes neuralgia and spasmodic twitchings in the stump, especially in females. No operative interference will be of the slightest use; and this condition must be treated, as best it may, constitutionally.

*Healthy Stump.*—Certain structural changes ensue in a healthy stump, and whereby it presents ultimately an altered appearance. The ends of bone or bones become rounded at their extremities, and the medullary canal occluded. The vessels are obliterated up to the nearest collateral branch, and the ends of the nerves have undergone some bulbous enlargement, consisting of dense fibro-cellular tissue and scattered nervous fibrillæ. The muscular portions of the flaps, however ample at first, are wasted and transformed into fibro-cellular texture connected with the skin, which chiefly forms the covering to the bone. The stump is thus reduced in size and somewhat pointed or conical; the rounded end of bone being plainly felt under the finger. The practical inference from this structural result is; that bulky muscular flaps are useless, and that the skin should be made of amply sufficient length to form the integumental covering of the bone.

*Artificial Limbs* of various kinds have been invented, suitable to the use of the part removed; and the most useful forms are figured in connexion with the result of each Particular Amputation.

**DOUBLE AMPUTATION.**—Amputation of two limbs, simultaneously or in immediate succession, may occasionally be required for severe injury, and sometimes for disease, as gangrene. The lower extremities are more frequently subject to double amputation, as when both thighs are crushed by the passage of a railway-truck across them; or one leg and one arm may have to be removed; but both arms seldom require amputation. I have had occasion to amputate both lower extremities, below the knees or in the thighs, in some instances; or the lower extremity, in the thigh, and the upper at the shoulder-joint; but I cannot call to mind having had occasion to amputate both arms.

The choice of simultaneous or subsequent amputation, must be determined by the state of shock to the nervous system and the circulation. The object of simultaneous amputation is to lessen the repetition and persistence of shock, by making it the shock, as it were, of one operation. But, the reserve-power of the system to sustain this single more severe

shock, must be judiciously estimated; and if subsequent amputation be deemed the safer course, the period of interval between the two operations—amputation of one limb, and then the other, should be regulated by the same consideration. In simultaneous double amputation of the lower limbs, Lister's tourniquet for compressing the abdominal aorta, offers the advantage of allowing the immediate succession of the second operation, without waiting to ligature the vessels in the first stump,—a procedure which involves no shock to the system.

RESULTS OF AMPUTATION.—The *mortality* after Amputation may be *primary*,—from shock; or from *secondary* causes,—principally, secondary hæmorrhage, exhaustion, tetanus, pyæmia, phlebitis, erysipelas, and pneumonia, or other visceral affections, and from affections of the stump, as sloughing, and Hospital gangrene.

The *causative conditions* which give rise to and induce these immediate causes, necessarily relate; (1) to the constitutional conditions, and age, of the individual; (2), to hygienic conditions; (3) to the operation;—as for injury or disease, the kind and extent of either, the period after injury,—representing primary and secondary amputations, the seat of amputation in its proximity to the trunk, and the structure of the bone sawn through, as involving or not the medullary canal.

(1) *Individual conditions*.—*Constitutional* states of health, whether hereditary or acquired, have a most powerful predisposing influence on the mortality after amputation, as after operations in general. A naturally *weak* constitution; in regard to the nervous system, the quality of the blood, as in the scrofulous diathesis, and the vigour of the circulation and of nutrition, predisposes severally, to the severity of shock contingent on the operation, to passive hæmorrhage, and to exhaustion. An acquired state of the general health, of similar character, in consequence of habits of intemperance and a hard life, resulting in a *broken* constitution, has the same unfavourable influence after amputation. Of *organic* diseases, the one which has perhaps the most fatal tendency, is Bright's disease of the kidneys, with albuminuria; a disease whereby the blood becomes drained of its albuminous or reparative plasma, and poisoned by the retention of urea or excrementitious matter. *Age* affects the result of amputation; the probability of success being in favour of an early period of life, and declining as life advances. In the one case, death occurs more frequently, by the exhaustion consequent on acute inflammatory fever, soon after the operation; in the other case, exhaustion from shock or from blood-poisoning, soon after the operation or at a later period.

(2) *Hygienic conditions* relate principally; to an impure atmosphere,—or as arising from deficient ventilation, defective drainage, or want of personal cleanliness, and to zymotic influences; also to the food, in respect to its quality and quantity. It is mainly on account of impure atmospheric conditions that the mortality from amputations in large towns contrasts unfavourably with those in the country. And, the causes of death are different; in towns, exhaustion, tetanus, pyæmia, erysipelas, and hospital gangrene; in the country; hæmorrhage and acute inflammation. But there is reason to believe that the principle now observed in the best Metropolitan Hospitals,—the segregation instead of the aggregation of patients, will tend to equalize the relative mortality after operations in town and country. At the Royal Free Hospital, where this principle is rigorously observed, pyæmia, for example, is of very rare occurrence.

(3) The *operation* itself, as to whether the amputation be performed for *injury* or *disease*, is followed by a very different rate of mortality, and in favour of disease. Thus, the mortality resulting from amputation in the thigh and leg, as performed in the Provincial Hospitals, differs considerably under these circumstances; being in regard to the thigh; 61 per cent., after amputation for injury, and only 23·4 per cent., after amputation for disease; and in respect to the leg; 40 per cent., as compared with 25·5. In the Parisian Hospitals, Malgaigne's statistics show less disproportionate results between the operation for injury and disease; in the thigh, 74 per cent., and 60 per cent.; in the leg, 63·3, and 49. But, after amputation of the foot; the proportionate mortality was 66·6 per cent., and 10·3 per cent.; and after the operation in the arm; 56·6, and 6·5. In University College Hospital, the results of 274 cases of amputation, in the thigh, leg and foot, shoulder and arm, and forearm, presented the following total proportion of mortality; for injury, in 92 cases, 36 deaths, or 39·1 per cent.; for disease, in 182 cases, 30 deaths, or only 16·5 per cent.

The causes of the greater relative mortality after amputation for injury, would appear to be; the greater severity of the shock, the tendency to pyæmia, the liability to tetanus, or to gangrene of the stump; whereas, exhaustion, or pneumonia, would seem to be the chief causes of a fatal result from amputation for disease. The *kind* and the *extent* of the local condition has also an unquestionable influence on the result of the operation; as illustrated by the importance of compound and comminuted fracture, and of malignant disease, in relation to their mortality after amputation. With regard to disease, a chronic state of the morbid condition, is least unfavourable for operation; as is well illustrated by the results of excision of the joints and bones.

The *period after injury* least unfavourable for amputation, has led to the distinction of primary and secondary amputations; the one being performed within the first twenty-four hours, or before the supervention of inflammation; the other, after that period, when inflammation has supervened, or at a later period, suppuration. The results of primary and secondary amputations differ in civil and military practice. In *civil* practice, the mortality from primary amputations is rather higher than from secondary amputations; but in a variable proportion according to whether it be the lower or the upper extremity, and the proximity of the operation to the trunk. In the lower extremity, and particularly in the thigh, primary amputation is most fatal. Of 46 cases, recorded by Malgaigne, 34 died. Of 24 cases, recorded by South, Laurie, and Peacock, as having occurred in old St. Thomas's Hospital, the Glasgow, and Edinburgh Infirmarys, all were fatal. The mortality increases the higher the operation is towards the trunk, and especially when performed for compound fracture of the femur, instead of for injury to the knee-joint or the leg. The total results of amputations in the thigh, leg, and foot, shoulder, arm, and forearm, as performed at University College Hospital, may be thus compared. Of primary amputations; in 48 cases, there were 18 deaths; of secondary amputations; in 43 cases, 19 deaths. In *military* practice, the mortality is reversed; secondary amputations, excepting those of the hip-joint, being far more fatal than primary operations. Of 300 secondary amputations by Faure, only 30 recovered; whilst three-fourths of Larrey's primary amputations re-

covered. With regard to whether the operation be performed in the upper or the lower extremity; during the Peninsular War, the mortality after secondary amputation in the one case was twelve times, and in the other, only three times, as great as after primary amputation of these parts; a difference more adverse to secondary amputation in the upper limb. The seat of operation in the upper and lower limbs, affects the mortality, as shown by the results in the British Army during the Crimean War. Thus, the relative rate of mortality per cent., was as follows. From primary amputations—at the shoulder, 27; of the arm, 17; of the forearm, 3; of the thigh, 62; of the leg, 30; and of the foot, 17. Then again, from secondary amputations, the death-rate per cent., in different parts, was; at the shoulder, 66; of the arm, 31; of the forearm, 28; of the thigh, 80; and of the leg, 76.

The cause of death, as well as the rate of mortality, differs after *primary* and *secondary* amputations. The former are more often fatal from shock, hæmorrhage, exhaustion, and perhaps tetanus, or pyæmia; the latter period of operation is especially prone to a fatal issue from exhaustion, tetanus, pyæmia, erysipelas, pneumonia, or other visceral affections, and to gangrene of the stump. But statistical results are wanting to accurately determine the relative frequency of these causes of death, as to the period of amputation, and their comparative frequency.

The *seat* of amputation, in relation to the mortality of this operation, has already been alluded to. The danger and the death rate are greater in proportion to the proximity of amputation to the trunk; and in an increasingly ascending ratio, the higher the line of operation, and the larger the size of the part amputated. Common surgical experience shows that the removal of a toe or finger is less hazardous than amputation of the thigh or arm. But statistical results have shown the regularly ascending mortality according to the line of amputation. Thus, in the American War, the percentage of mortality rose as follows:—fingers and hands, 1·5; wrist, 5·5; forearm, 16·5; arm, 21; shoulder, 39; partial of foot, 9; ankle-joint, 13; leg, 26; knee, 55; thigh, 64; and hip, 85. Some relation subsists between the proximity to the trunk and the causes of death, from amputation. Thus, the removal of a limb high up, is more fatal from shock, or hæmorrhage, primary or secondary.

The *structure* of the bone sawn through, when the medullary canal is opened, seems to have some degree of unfavourable or even fatal influence; owing to the liability of consecutive suppurative inflammation of the medullary membrane,—osteomyelitis, and pyæmia. But the importance of this condition relatively to the mortality after amputation, is very undetermined.

#### PARTICULAR AMPUTATIONS.

AMPUTATIONS OF THE UPPER EXTREMITY.—THE HAND.—*The Fingers; at their Phalangeal Articulations*, not unfrequently require amputation; for injury, or disease, as caries resulting from whitlow. This operation is very simple. The hand being held prone, and the fingers on either side of the affected one drawn towards the palm by an assistant; the operator lays hold of the end of the finger, and bending it slightly, he applies a narrow-bladed bistoury or scalpel to one side of the joint, opposite the articulation (Fig. 279), and carrying it over to the opposite side, makes a slightly convex incision, directed downwards; then, running

the knife across and through the joint, bending it as needs be, the blade is turned flat under the phalanx, and the semilunar flap made of sufficient length to cover the extremity of the bone and unite with the dorsal incision. *Another and reverse mode* of doing this operation is; by placing the hand in the supine position, and with the finger extended, to transfix on the palmar aspect of the joint, and carrying the blade flat on the bone, cut a semilunar flap of sufficient length; then, passing the knife across and through the joint, to divide the skin almost transversely in bringing it to the surface.

FIG. 279.

*Amputation through any of the Phalanges*, may be performed in like manner.

*Amputation of the entire Finger, at the Metacarpo-phalangeal Articulation.*—Having placed the hand in the prone position with the fingers, on either side of the affected one, drawn towards the palm by an assistant ;

FIG. 280.

FIG. 281.

the point of a long narrow bistoury or scalpel is entered on the dorsal aspect of the metacarpal bone about half an inch above the head of this bone or knuckle, and carrying the incision forward to the interdigital web, and round the palmar aspect of the finger, the knife is turned obliquely backwards along the interdigital web of this side also, to join

the dorsal incision. A kind of looped incision is thus formed, embracing the root of the finger from above the joint and there including an angular portion of integument. The oval flap is easily drawn back, the extensor tendon divided across, and the finger disarticulated. (Fig. 280.) The bulky head of the metacarpal bone had better then be removed with bone-forceps, introduced from the dorsal surface, and by nipping the bone cleanly across (Fig. 281); unless it be the index or little finger, in regard to both of which the bone should be nipped across obliquely from without inwards so as to conform to the outline of the hand. After tying or twisting the digital arteries, the edges of the incision readily fall together into a line, and the fingers being brought together, the gap is scarcely perceptible. A palmar splint is applied, and simple dressing as usual. The *Metacarpal bone* may be included by carrying the incision further back; but it is better to leave the base of the bone,—not to open the wrist-joint, and care should be taken not to wound the palmar arch in removing the bone from its bed.

FIG. 282.

Several Fingers, with perhaps their metacarpal bones, requiring removal for disease or injury; the operation can be fashioned in a similar manner, leaving a very useful forceps-hand. (Fig. 282.)

*Amputation of the Thumb, at its Carpo-metacarpal Articulation,* is the only amputation peculiar to the thumb.

Commencing an incision just above the articulation of the base of the metacarpal bone with the trapezium, and continuing it down the dorsal aspect of the bone, inclining slightly to the radial side, the knife is sunk into the fold of integument between the thumb and forefinger (Fig. 283); then introducing the knife at this extremity of the incision, and thrusting it up along the palmar aspect of the bone, its point is made to emerge at the commencement of the incision, and the palmar integument divided outwards. The bone is twisted out, and disarticulated with a few touches of the knife, the lips of the oval wound form a single incision, and eventually a linear cicatrix. By this, or Liston's method of amputation, there is a *single* line of incision. In operating on the right thumb, it will be necessary for the Surgeon to cross his hands, in an awkward manner; unless he is ambidextrous. *Another method* consists in carrying the dorsal incision downwards to within half an inch of the metacarpo-phalangeal articulation, and then in an oval form around the joint, up to the dorsal incision. When the flap is brought together, there will still be only a single line of *cicatrix*.

FIG. 283.

*Amputation of the Little Finger, at its Carpo-metacarpal Articulation, may be performed in a similar manner.*

**AMPUTATION AT THE WRIST-JOINT.**—The radio-carpal articulation is as easily opened as any of the joints in the hand. An assistant holding the forearm, the operator lays hold of the hand on its palmar aspect, with his forefinger and thumb on the styloid processes of the radius and ulna; thus spanning the wrist, as the limits of the incision. A short narrow-bladed amputating-knife is used instead of a bistoury, and an incision made from one styloid process to the other, across the back of the joint, slightly curving towards the hand. (Fig. 284.) Passing the knife across the joint, clear of the arched-shaped surface of the carpal bones, the lateral ligaments are divided, and the knife carried forward on the palmar surface of the metacarpal bones, so as to make a rounded flap of sufficient length to cover the ends of the radius and ulna, and unite with the dorsal incision. In turning the knife round the joint, care must be taken not to hitch against the pisiform bone, which projects forward, on the palmar aspect, beyond the other bones of the carpus. The radial and ulnar arteries will require ligature or torsion, and perhaps some interosseous carpal branch.

FIG. 284.

An *artificial hand* may eventually be adapted to the stump; one of the most useful forms is here represented (Fig. 285), and one of its most important uses. (Fig. 286.)

FIG. 285.

**AMPUTATION OF THE FOREARM.**—The middle of the forearm is the part to be preferred for amputation, as affording the most convenient coverings to the stump, and a tolerably suitable length of stump for the application of an artificial hand. The brachial artery must be commanded by an assistant, and the forearm held by another assistant, in a state of extension and semi-pronation,—the radius looking upwards. The margins of the bones should be felt by the operator with one hand; a posterior flap is then made by a curved incision downwards; commencing on the palmar margin of the radius, on the left side, and continued a little way

down along the bone, arching across the back of the forearm, and up along the ulna to a point on its palmar aspect opposite to the other horn of the incision, it thus extends forward sufficiently on either side for easy transfixion in front of the bones. (Fig. 287.) This flap is reflected by

FIG. 286.

a stroke or two with the knife; and the point being entered at one horn of the incision, in front of the bones, and made to emerge at the other, an interior flap of corresponding shape and length, is formed by carrying the knife from within outwards, along the surface of the bones. Both flaps are retracted by an assistant. Sweeping the knife around the bones to divide any remaining muscular fibres and cutting across the interosseous membrane with the point of the instrument; the bones are then sawn together. The radial,

ulnar, and interosseous arteries in the anterior flap, must be ligatured or twisted, and the flaps adjusted with sutures.

This method of performing amputation of the forearm, provides for

FIG. 287.

easy transfixion, and is the most dexterous; but in a similar position of the forearm,—semi-pronation, both flaps may be made by transfixion.

*An artificial forearm* may be fitted thus (Fig. 288). It is a modification by Mr. Bigg, of Beaufort's arm. The hand may be adapted for a variety of important movements—as in writing or driving.

**AMPUTATION OF THE ARM.**—An assistant compressing the brachial artery, the Surgeon makes a couple of equal flaps, an anterior and a posterior, simply by transfixing the arm in front of the humerus, and cutting a well-rounded flap, and then entering the knife behind the bone and making another such flap. (Fig. 289.) These are retracted by an assis-

tant. A sweep of the knife clears the bone, which is then sawn through; care having been taken that the musculo-spiral nerve was divided by the knife at the back of the bone—if the amputation be at that part of the arm where this nerve winds round behind the humerus. The artery, and any bleeding branches of magnitude, are secured, and the flaps brought together.

Circular amputation, as in the thigh, will be preferable, if the limb be very fleshy.

*Results.*—Amputations of the forearm, or of the arm, are very successful. For disease, as of the joints or bones, amputation is especially successful; but far less so for malignant disease. For injury, the operation in either part is more fatal; the death-rate per cent. rising, as usual, relatively to the amputation nearest the trunk. Thus, during the American War, the proportion was, after amputation of the forearm, 16·5; the arm, 21. In the Crimea, amputations of the forearm were fatal in the ratio of only 7, and those of the arm 19, per cent. At University College, in Mr. Liston's and Mr. Erichsen's practice; in 8 traumatic amputations of the forearm, all recovered; whereas, of 11 such amputations of the arm, there were four deaths. At Guy's Hospital, according to Mr. Byrant's statistical results, the ratio of fatal traumatic

FIG. 288.

FIG. 289.

amputations of the forearm and arm, was, 16, and 22, per cent.; thus almost exactly equalling the proportionate mortality during the American War. And this comparative result was in *Civil* and *Military* practice, respectively.

An *artificial arm* may be adapted to the stump; and of the various

FIG. 290.

FIG. 291.

forms invented, the best construction is Van Petersen's, if the stump be long and mobile (Fig. 290); or the less costly arm invented by Count de Beaufort (Fig. 291).

**AMPUTATION AT THE SHOULDER-JOINT.**—An assistant standing above the shoulder, compresses the subclavian artery as it passes over the first rib; or if he know the operation practically, he may be trusted to catch the artery with his thumbs in the inner flap. Another assistant holds the arm up so as to relax the deltoid muscle. The Surgeon—operating on the *left* arm—introduces a long-bladed amputating-knife at the posterior border of the axilla, and passing it in front of the joint, makes it emerge at the anterior border of the deltoid muscle, about an inch below the point of the acromion; cutting downwards and outwards, a large flap is formed chiefly of the deltoid muscle and skin. This flap is raised by an assistant at the shoulder, and the arm brought down towards the front of the chest; thus presenting the head of the humerus and muscles attached to the tuberosity. Running the knife across the joint, these are divided, with the capsular ligament, and the knife turned to the inner side of the joint (Fig. 292), followed by the hand of another assistant ready to compress the artery. The arm is again raised to give freedom in making the flap, and the knife carried downwards close to the bone, forming an inner flap corresponding to the outer one; while at this moment, the assistant in charge grasps the whole thickness of the inner flap with both hands, between his fingers and thumbs crosswise, and catches the artery as it is divided. If this be done dexterously very little blood escapes. Amputation at the *right* shoulder-joint is performed in precisely the same way, only that the shoulder is transfixed from before backwards, the knife being entered in front of the deltoid about an inch below the acromion, and made to emerge at the posterior border of the axilla. The axillary

artery and other vessels having been tied or securely twisted, the flaps are adjusted with sutures.

FIG. 292.

*Results.* — Amputation at the shoulder-joint, for disease of the humerus, is more successful than the same operation for injury, the mortality, in the latter case, amounting to 35 during the Crimean War. The death-rate per cent. in the American War was 39; that after amputation in the arm being only 21 per cent., a difference of 18 adverse to amputation at the shoulder-joint. The injury requiring amputation, as compound fracture of the humerus high up, is usually accompanied with other injuries, particularly of the head, thus increasing the risk of a fatal result.

#### AMPUTATIONS OF THE LOWER EXTREMITY.

**THE FOOT.**—*Amputations of the Toes, at their Phalangeal Articulations, and at their Metatarso-phalangeal Articulations.*—These operations are performed in a manner precisely similar to the analogous operations on the Fingers. In amputations at the last-named articulations, the incision must be commenced proportionately farther back than in the Hand, these articulations being situated at some distance above the web of the Toes (Fig. 293); and it is undesirable to remove the head of the metatarsal bone, which would diminish the breadth and support of the foot.

*Amputation of the Great Toe, at its Tarso-metatarsal Articulation.*—With a stout bistoury, commence an incision on the dorsum of the foot, at the posterior extremity of the interspace between the metatarsal bones of the first and second toes; carry the incision forward to the ball of the great toe, and curve it inwards upon the ball to the sole of the foot, at a part opposite to the web between the toes; thence draw the knife backwards along the sole of the foot, parallel with the outer margin of the metatarsal bone of the great toe to a point opposite to the commencement of the dorsal incision. Dissect the flap back, close to the bone; divide

the web between the first two toes, avoiding the sesamoid bone here situated, and isolate the metatarsal bone; then twisting the great toe inwards, pass the knife deeply into the angle of the wound and open the

FIG. 293.

FIG. 294.

articulation with the internal cuneiform bone, detaching its ligamentous connexions; and thus complete the amputation. (Fig. 294.)

The *metatarsal bone alone* can be removed by the first part of this operation; the flap being made without then dividing the web of the toes.

*Amputation of the Little Toe, at the Tarso-metatarsal Articulation.*—This operation is analogous to that for the removal of the Great Toe; but the line of incision is here *single*. The knife is entered just behind the prominent tubercle of the metatarsal bone of the little toe, and carried inwards and forwards in the oblique line of its articulation with the cuboid; thence into the fourth metatarsal interspace forward to the web of the toe, and around under the toe, back into the incision on the dorsum of the foot. The integument is dissected off, exposing the metatarsal bone, the bone isolated; and, the toe being forcibly drawn outwards, the joint is opened in the angle of the wound, and the operation completed.

*Amputation of the whole of the Toes, at their Tarso-metatarsal Articulations.*—*Hey's Operation.*—This amputation is performed by a dorsal incision, slightly curved downwards, and a plantar flap, the limits of which transversely are the tubercle of the metatarsal bone of the little toe and the base of the first or the tubercle of the scaphoid bone in preference; the flap extending forward sufficiently to cover the ends of the tarsal after disarticulation of the metatarsal bones. The leg is placed with the foot downwards, and steadied by an assistant; the Surgeon grasping the fore-part of the foot and feeling with his finger and thumb the points of bone above mentioned, he makes a semilunar incision from

the one to the other across the back of the foot, cutting down to the bone and reflecting this short flap of integument. (Fig. 295.) Passing the

FIG. 295.

knife under the bases of the metatarsal bones from one horn of the incision to the other, and transfixing the foot, a longer flap is made from the sole of the foot. (Fig. 296.) The irregular line of articulations is then

FIG. 296.

opened with the point of the knife, while the fore-part of the foot should be forcibly depressed to facilitate disarticulation. The plantar flap is adjusted with sutures, and a single cicatrix remains on the dorsal aspect of the stump. (Fig. 297.)

FIG. 297.

*Amputation through the Tarsus*,—in the line of articulation between the astragalus and os calcis, posteriorly, and the scaphoid and cuboid bones, anteriorly.—*Chopart's Operation*.—The guides to this operation are; the tubercle of the scaphoid bone on the inner side of the foot, and a point about half an inch behind the tubercle of the fifth metatarsal bone on the outer side of the foot, or about midway between this projection and the front of the outer malleolus. The

operation is similar to Hey's, only that the incisions are commenced further back (Fig. 298); the dorsal curved incision is made between the points

FIG. 298.

of bone above named; the tarsal bones must then be disarticulated; and the plantar flap formed, keeping the knife well turned towards the under,

FIG. 299.

concave surface of the metatarsal bones, and extending this flap, forwards to the root of the toes, where it should be rounded off across the sole of the foot. The vessels are thus left uninjured, and an ample cushion formed. The head of the astragalus had better be sawn off; and the tendo-Achillis, which is apt to tilt this bone forward, may be divided by subcutaneous section at the time of the operation, or subsequently. The stump, as compared with that made by Hey's amputation, is here represented. (Fig. 299.)

**AMPUTATION AT THE ANKLE-JOINT.—Syme's Operation.**—This amputation consists in making a posterior heel-flap, and an anterior incision across the joint; disarticulating the foot, and taking a slice off the end of the tibia. The foot projecting over the end of a table, and at a right angle to the leg; a stout bistoury is entered at the centre of one malleolus, and drawn downwards and slightly

FIG. 300.

backwards, under the prominence of the heel, upwards and forwards to a corresponding point at the other malleolus. Or, the heel-incision may be carried slightly forwards. (Fig. 300.) The flap, marked out

by this incision, is dissected back to the tendo-Achillis; the operator placing his fingers upon the heel, while his thumb rests upon the edge of the flap, he cuts between the nail of the thumb and the tuberosity of the os calcis, pressing back steadily at the same time. In reflecting the integument round the tuberosity, the risk of making a button-hole will thus be avoided; and by still keeping the knife close to the bone on the inner side of the os calcis, the plantar arteries are not injured. An incision is next made from one upper extremity of the heel-flap, across the dorsum of the foot to the other extremity; then, depressing the foot, the joint is opened and the lateral ligaments divided by the point of the knife; the astragalus is disarticulated, and the tendo-Achillis divided, as also any slight connexion of the os calcis, and the foot removed. A thin slice is sawn off the end of the tibia, including the two malleoli. The plantar arteries are secured, and the heel-flap is brought forward to the anterior incision and retained by sutures. An excellent stump often results, with only a transverse line of cicatrix. (Fig. 301.)

FIG. 301.

Professor Pirrie makes a slight modification of this amputation, by sawing off the ends of the bones, *without* previous disarticulation of the foot; thereby shortening the operation.

*Pirogoff's operation* is a modification of Syme's. It consists in preserving the posterior portion of the os calcis, which is retained in the heel-flap. This flap is reflected back about two lines; the anterior incision is made, the astragalus disarticulated, and the malleoli sawn off with a thin slice of the tibia; then, the saw is entered behind the astragalus on the upper and back part of the os calcis, which is sawn obliquely downwards and forwards. The posterior portion of the calcaneum, thus left, is brought up into contact with the tibia; leaving the tendo-Achillis undivided, and forming a longer stump for support. The osseous surfaces readily unite.

The chief advantages of this operation are; the increased length of stump, and the less liability to sloughing of the heel-flap,—the plantar arteries always being cut long and the general vascular communications remaining undisturbed. The disadvantages are; the greater liability to osteo-phlebitis, owing to the section of two osseous surfaces; and the recurrence of disease in the portion of calcaneum left in the heel-flap. This latter objection, however, does not apply to the amputation when performed for injury.

Professor Pirrie has devised a simplification of this operation also, and one which includes his modification of Syme's amputation. The os calcis is sawn from *below*,—upwards and backwards; and then—having made the anterior incision—the tibia and fibula are sawn through just above the malleoli, without previous disarticulation of the foot.

*Sub-astragaloid Amputation*.—Removal of the foot below the astragalus is analogous to Syme's amputation; that bone being left and the operation performed between it and the calcaneum, at the articulation of these bones. A heel-flap having been made as in Syme's amputation;

an anterior incision lays open the articulation between the astragalus and scaphoid bone, as in Chopart's amputation; the knife is then passed backward between the astragalus and calcaneum, dividing their interosseous and other ligamentous connexions, and the foot is removed. A longer, and so far more useful stump remains than after Syme's amputation at the ankle-joint; but sub-astragaloid amputation is comparatively rarely eligible,—only when the astragalus is not involved.

*Hancock's Operation*—consists in amputation of the foot below the astragalus, leaving the posterior third of the os calcis, which is turned up against the under surface of the astragalus, prepared for its adaptation and union therewith by also removing the under surface and head of this bone. This operation, therefore, bears the same relation to sub-astragaloid amputation, that Pirogoff's operation does to Syme's amputation at the ankle-joint. As an improvement on sub-astragaloid amputation, Hancock's amputation provides a more advantageous stump, in two essential points; namely, the length of the limb, and the amount of leverage afforded by the astragalus for the artificial foot, and the consequent effects upon the movements of the ankle-joint. This operation would seem to be suitable for disease or injury involving the tarsal bones, excepting the astragalus, and when limited to the anterior portion of the os calcis. It was originally performed by Mr. Hancock in the winter of 1864-5, and in the only case so far as I know in this or any other country; the case was one of scrofulous disease, which presented the requisite conditions for this amputation. The result was perfectly successful; complete union taking place between the section of the os calcis and astragalus, and the patient having a most useful stump. He was exhibited at the Royal College of Surgeons, in June 1866, one year and a half after the operation; when, among many other observers, I had the opportunity of examining the permanency of this result.

The particulars, therefore, of the original operation possess some historical interest; and as illustrating the plan and performance of an amputation not hitherto described in Surgical works, I shall here introduce Mr. Hancock's description :—"I commenced an incision beneath and at the posterior angle of the external malleolus, and carried it forwards along the outer border of the foot to a point about half an inch anterior to the projecting base of the fifth metatarsal bone. I then made a second incision along the inner border of the foot, commencing posteriorly about the centre and beneath the internal malleolus, and terminating anteriorly at a spot corresponding to the termination of the external incision; and then united the two by a third and semilunar incision, carried, with its convexity directed towards the toes, across the front of the sole of the foot well down to the bones. Reflecting this flap back as far as the projections on the under surface, and in front of the tuberosity of the os calcis, I carried a fourth incision across the dorsum of the foot, immediately behind the head of the astragalus. Then, applying a saw upon the under surface of the os calcis as far back as I could, I cut through the bone obliquely from below upwards and backwards. Next, resuming the knife, I entered the medio-tarsal articulation, and, passing the instrument under the head of the astragalus, and cutting from before backwards, in the direction of the anterior articulating surface on the os calcis, divided the interosseous ligament, and detached the front of the foot. I then sawed off the head of the astragalus, and with a pair of bone-cutters, curved on the flat, removed the two articular cartilages on the under

surface of this bone, and securing the two plantar arteries, thus completed the operation. The flaps were brought together by three wire-sutures in front, the lower angles of the wound being left open. No suppuration ensued in the course of the tendons, no secondary hæmorrhage, nor any constitutional disturbance."

*Results of Tarsal and Ankle-joint Amputations; see EXCISIONS.*

After any of these amputations, at, or immediately below, the ankle-joint, an *artificial-foot* may be adapted. A common, and cheap form, is a

FIG. 302.

FIG. 303.

leathern-hood, not unlike an elephant's foot (Fig. 302); or Bigg's artificial foot will be a complete apparatus. (Fig. 303.)

**AMPUTATION OF THE LEG.**—An assistant commands the femoral artery by digital pressure or compression with a tourniquet, and the leg projecting beyond the edge of a table, should be held horizontally by another assistant seated on a low chair or stool. The Surgeon standing as usual so as to grasp the limb below the seat of amputation, enters the point of

FIG. 304.

the knife at the posterior edge of the tibia—on the left leg, carries it downwards on the bone for about an inch and a half, curves the incision across the anterior aspect of the leg to the posterior margin of the fibula, and up that bone to the point opposite its commencement on the tibial side. (Fig. 304.) The flap is reflected by a few touches with the point

of the knife, which is then made to transfix the limb behind the bones from one horn of the anterior flap to the other—care being taken not to lock the instrument between the bones—and by cutting obliquely downwards and backwards, a long posterior flap is formed. The interosseous membrane is divided transversely, with the point of the knife, and a sweep round the bones clears a line for the saw. In

FIG. 305.

applying the saw, the fibula should be divided first; otherwise, as a slender long bone, it will be splintered; and the tibia had better be sawn obliquely from before backwards, to make the anterior flap lay more easily than it would on the sharp ridge of a transverse section of the bone. Any projecting spiculous portion of bone must be clipped off with cutting-pliers. The arteries requiring ligature or torsion, vary with the situation of the amputation; in the middle third of the leg, the anterior and posterior tibials between the bones of the stump must be tied; in the upper third just below the knee, the popliteal trunk may not have bifurcated, and one artery alone may have to be ligatured. (Fig. 305.)

Another mode of performing this amputation is; by transfixion and the formation of a posterior flap first, and then the anterior semilunar flap.

The stump, in either case, is apt to bag and drop, owing to the bulk and weight of the posterior flap; which is not less than three inches in length, and bulky in proportion to the muscular development of the calf.

*Teale's amputation*, by a long anterior and a short posterior rectangular flap. This operation obviates the difficulty last referred to; but its comparative merits in other respects, as a mode of amputation, have been already considered.

*Artificial legs* are here represented; the common form, a wooden or "box-leg" (Fig. 306), the more complete leg (Fig. 307).

*Results.*—Amputation of the leg, is, on the whole, a successful operation; but, like other amputations, the mortality differs according to whether the operation be performed for disease or injury, and the nature, and the situation of either. For disease, the average death-rate per cent., is 25.5; whilst, for injury, it rises to 26, as in the American War; 37, as in the Crimea; or even 40 per cent., as in the London and Provincial Hospitals during a period of three years. Primary amputation, is generally more fatal than secondary; but, Mr. Bryant's statistics of cases in Guy's Hospital, seem to reverse this rule; at the one period of operation the mortality being 62 per cent., and at the other or secondary period, amounting to 66 per cent. Proximity to the knee-joint, increases the risk of amputation.

**AMPUTATION AT THE KNEE-JOINT.**—Two methods of performing this operation are occasionally practised; by a short anterior and long posterior flap, or by a long anterior and short posterior flap.

Operation by a *short anterior and long posterior flap*.—A transverse or slightly curved incision is made across the knee-joint, above the patella,

FIG. 306.

FIG. 307.

from condyle to condyle of the femur; the extensor tendon, lateral ligaments, and crucial ligaments, are successively divided, and the joint fairly opened; the knife is inserted behind the tibia, a

long posterior flap cut downwards and backwards from the upper part of the calf of the leg, and the leg removed. (Fig. 308.) The articular sur-

FIG. 308.

face of the femur is then sawn off, the popliteal artery tied or twisted securely, and the flaps brought together with sutures. The stump made by this amputation, may be most excellent, and as a permanent result. It was so in a case, after this mode of operation, by Sir W. Fergusson, in 1845. Since that time, the man has repeatedly walked forty miles a day, with a very indifferently made artificial leg; and on one occasion, a

hundred and twenty miles in three days, without the slightest damage to the stump. (Fig. 309.)

FIG. 309.

Operation by a *long anterior and short posterior flap*.—An incision is made from one condyle to the other, extending below the patella; the ligamentum patellæ must then be divided, and the flap of integument, including the patella, reflected; the lateral and crucial ligaments having been divided, the knife is passed behind the tibia, and a short abrupt flap cut outwards. The operation is then completed as before. The patella had better be left, for protection of the stump; but the cartilaginous surface of the condyles may be advantageously sawn off.

SUPRA-CONDYLOID Amputation may be performed in like manner as the operation at the Knee-joint.

The advantages of both these amputations,—through, or just above the knee joint, as compared with removal of the limb higher up, are three. They relate to the results of operation,—both in regard to mortality, and the kind of stump.

*Results.*—Of 49 cases of amputation through the knee-joint, collected by Dr. Markoe, 17 were fatal; being a mortality of 37 per cent., or about half the percentage, 64, of amputation in the thigh, during the American War. But in that War, the death-rate was 55 per cent. after amputation at the knee-joint. The results of supra-condyloid amputation have not yet been indicated by statistics, in relation to its mortality. But, like the operation through the joint, it may fairly be inferred that this operation also is far less fatal than amputation in the thigh; the medullary canal of the femur not being opened in the two former amputations. The results with regard to the *stump* are certainly very advantageous; a long stump is provided for the adaptation, and more convenient use, of an artificial limb; and, after the operation with a long anterior flap, the end of the stump is well covered by integument, and thus protected from the risk of excoriation from pressure, as the cicatrix lies altogether behind the surface.

AMPUTATION OF THE THIGH.—An assistant compresses the femoral artery, and another sitting on a stool, holds the leg so that the thigh shall be horizontal, and project from the buttock over the edge of a table. The Surgeon with his left hand lays hold of the fleshy part of the thigh in front of the bone and raises it a little, then introducing a long-bladed

amputating knife just in front of the femur and transfixing the thigh, an anterior flap is made by cutting downwards and outwards to the surface. (Fig. 310.) Entering the knife again, about an inch lower than the upper

FIG. 310.

limit of the former incision, and passing it behind the bone to the same point on the other side of the thigh, a posterior flap is made of corresponding length and shape. The advantage of re-entering the knife as directed, is not to jag the integument by the alteration of level necessary

FIG. 311.

to transfix the thigh, in lowering it under the bone. Both flaps should be now retracted by an assistant, the knife swept round the bone at the highest point, and the bone sawn transversely across by a light vertical action of the saw. (Fig. 311.) The leg-assistant must observe to evenly

support the limb, as the bone is divided; not to lock the saw by elevating the limb, nor to snap and splinter the bone by allowing the limb to drop. The artery and any muscular branches must then be seized with artery-forceps (Fig. 312), and secured by ligature; or by acupressure, or torsion; and the flaps evenly adjusted with sutures.

FIG. 312.

The *circular method* of amputation may be preferred, especially in a very muscular thigh (see p. 682).

*Amputation of the Thigh, by Lateral Flaps,—Vermale's operation.*—In the lower third of the thigh, amputation is best performed by lateral,—instead of antero-posterior flaps; the sides of the thigh, in this part, being more fleshy, and better fitted for the formation of a stump. The surgeon grasping the soft parts, on the outer side of the thigh, with his

FIG. 313.

left hand, and drawing them outwards from the side of the femur; the knife is entered perpendicularly in the middle of the thigh, about three inches above the upper border of the patella, and thrust downwards close round the bone, and brought out in the centre of the ham (Fig. 313);

the flap then being cut downwards and outwards. The knife is again entered, at the upper angle of the incision, the thigh transfixed close to the side of the bone, and the point being brought out at the lower angle of the incision, a corresponding inner flap is made in like manner. Unless the blade be passed around the bone on this aspect of the thigh, the femoral artery is very apt to be split. The flaps are retracted, the bone cleared by a sweep of the knife, and the saw applied about four inches above the condyles.

*Forms of Artificial Leg.*—(1) *Bucket-leg* (Fig. 314)—A, a hollow sheath or bucket, accurately conformed to the shape of the thick stump; B, the pin, for support; C, strap. This leg, as well as the one already noticed for amputation *below* the knee, is in common use, by soldiers and sailors, or others of the working classes. (2) *Bucket-leg*, with substitute *mechanism* for leg below the knee (Fig. 315)—A, bucket; B, knee-bolt;

FIG. 314.

FIG. 315.

C, D, E, situation of springs, for mock muscles, governing the action of the ankle and toe-joints. (3) *Bly's leg*, of Rochester, New York (Fig. 316)—B, ball of polished ivory, for movements of ankle-joint; C, cords having the position and functions of the natural tendons; S, indicates three of the five india-rubber springs, as muscles; N, position of the nuts, for regulating tension of cords and springs; E, spring, acting on knee-joint. 2 represents ankle-joint flexed diagonally, as often occurs, when one side of the foot happens to rest on a stone or other obstacle in walking. (4) *Bigg's leg*, a modification of Bly's and Mark's legs. (Fig. 317.) This is, perhaps, the simplest, strongest, lightest, and cheapest artificial leg or limb ever constructed. A gentleman, who had for years used limbs of other construction, wrote to Mr. Bigg, saying—"I never knew what comfort was with an artificial leg, until I adopted yours; it enabled me to walk to the Boat Race, and stand six hours about upon it."

Other forms of artificial leg are, the old Anglesea leg, as used by the Marquis of Anglesea, after the battle of Waterloo; the Palmer leg; and Mark's leg, an American invention.

*Results.*—Amputation of the thigh is more fatal than any such operation, except that at the Hip-joint. In the American War, the percentage

FIG. 316.

FIG. 317.

of mortality was 64, after amputation for injury. But the period of the operation, as primary or secondary, makes some difference in the mortality, and in favour of primary amputation, unless when performed for compound fracture of the femur, instead of for injury to the knee-joint or the leg. For disease, amputation of the

thigh is less fatal, except for acute disease of the knee-joint.

**AMPUTATION AT THE HIP-JOINT.**—This operation, so fatal in its results, is less formidable in its performance. The patient lying with his buttock on the edge of the table, an assistant supports and governs the limb; another assistant, standing at the pelvis on the side of operation, compresses the artery above the brim of the pelvis, and is ready to take charge of the vessel when divided in the first incision. Or, the risk of hæmorrhage may be guarded against, by means of Lister's compressor of the abdominal aorta. The Surgeon, standing as usual with his left hand towards the distal part of the limb, selects the longest-bladed amputating-knife; introducing it—in the *left* limb—about midway between the anterior superior spinous process of the ilium and the great trochanter, he thrusts it directly across the joint, so that its point shall emerge just above the tuberosity of the ischium (Fig. 318), the scrotum being drawn away and protected by an assistant. The knife, thus transfixing the root of the thigh, is carried rapidly downwards and forwards to the surface, cutting an anterior and inner flap, about five or six inches in length, and the breadth of the thigh. The assistant, at the pelvis, closing his hands into

the wound from either side, catches the femoral artery in the under-surface of this flap, between his fingers beneath and thumbs over the flap.

FIG. 318.

The limb should now be forcibly abducted and everted by the leg-assistant; the capsule opened from the inner side by drawing the knife firmly across, when, with a touch on the round ligament, the assistant depressing the limb, the bone starts from its socket. The knife is then laid on, about its middle, behind the head of the femur, the remainder of the capsule divided, and by drawing the knife downwards and backwards through the muscles, a shorter posterior flap is fashioned to meet the anterior one. The artery, and any muscular branches having been secured, and the large cavity well sponged with cold water; the two flaps are brought together with sutures, and a large compress applied. On the *right* limb, the operation is the same, only that the knife is *entered* in the reverse directions—namely, just above the tuberosity of the ischium.

This method of amputation at the hip-joint, by anterior and posterior flaps, is substantially the same as that recommended by Liston.

By the same mode of operation, also, the femur can be sawn through *below the trochanters*, in fracture of the shaft high up, or disease affecting the shaft below; thus leaving the head and neck of the bone, with ample flaps to cover. I have amputated just below the hip-joint for disease of the femur, consequent on typhoid fever, and with an excellent stump resulting.

The above-described amputation will have to be modified by various conditions of injury necessitating the operation, but which require its adaptation to the state of the integuments, as affected by the extent of contusion and the situation of wounds. The flaps must be contrived so as to meet these difficulties.

In a case of "severe compound comminuted fracture of the right femur," for which I had to perform amputation at the hip-joint, the operation was modified by the state of the integuments. The particulars of this operation were well reported, in the *British Medical Journal*, by Mr. C. S. Jeaffreson, then Senior House Surgeon to the Hospital. "On the after-

noon of March 15th, a man, aged 26, was brought to the Hospital from the Great Northern Railway. By some accident he had slipped under a railway truck, which passed over his right thigh, just above the knee-joint. The injuries he received were more difficult to describe than imagine; suffice it to say, that the greater portion of the integuments were torn from the entire limb, the muscles of the thigh reduced to a sort of pulp, and the bone splintered into many fragments. There was considerable arterial hæmorrhage, to stop which I placed a ligature round the femoral artery in Scarpa's triangle. The shock to the system, though very severe, was not so intense as one could have expected from such a frightful injury. The patient earnestly desired that his limb might be immediately removed. The margin of the wounded integuments was obliged to be taken as the line of incision, otherwise no skin could have been obtained to cover the stump, thus a kind of oval amputation was performed as follows: the knife was entered just below the middle of Poupert's ligament; it was then drawn obliquely downwards and inwards, crossing the back of the thigh, and prolonged upwards and inwards to the point of its departure; in this way an oval flap was made from the integuments of the back of the thigh and buttock. The muscles were then divided, the femoral artery secured, and the head of the femur turned out of the socket. Although little hæmorrhage resulted from the operation, the patient towards its end showed symptoms of severe collapse. On being placed in bed, he recovered from chloroform, but expired within three hours of the operation. This case, though of no special interest, illustrates very well one point in connexion with the practice of amputation after severe injuries—*i.e.*, that the Surgeon must not always expect to be able to follow any one particular operation as laid down in books, but in many cases must exercise his own ingenuity in the manufacture of a stump from what may be aptly called the wreck of the injured limb."

*Results.*—Amputation at the hip-joint is an operation of fatal result in the great majority of cases; in 126 cases, 76 died. But the mortality differs considerably according to whether the operation be performed for disease or injury. Thus, in 42 hip-joint amputations for chronic disease of the femur, 18 died; whereas, in 47 for injury, 35 were fatal; and the death-rate percentage was 85 during the American War. Primary amputation for injury is the most fatal; in 30 cases, collected by Legouest, all died; and in another 12, during the Crimean War, all died. In the American War, however, of 19 cases, 2 recovered. Secondary amputation for severe injury to the femur has been singularly successful; of 9 cases in America, 2 recovered; and in 4 cases, by J. Roux during the French Campaign of 1859 in Italy, all recovered. Re-amputation at the hip joint, for diseased thigh-stumps, has proved successful in 4 out of 7 American cases.

## DIVISION II.

### INJURIES AND DISEASES OF ORGANS AND REGIONS.

---

#### THE HEAD.

---

#### CHAPTER XXXIX.

##### INJURIES AND DISEASES OF THE SCALP, CRANIUM, MEMBRANES OF THE BRAIN, AND BRAIN.

**INJURIES OF THE SCALP.—WOUNDS.**—The integument covering the skull is liable to wounds resembling those of the soft parts in any other situation. Scalp-wounds may therefore be incised, or lacerated and contused; and these lesions are of very common occurrence. They have two peculiarities worthy of notice—a marked tendency to heal by primary adhesion, however extensive the wound and detachment of the scalp from the pericranium; and, on the other hand, a special liability to the supervention of erysipelas, suppuration, and sloughing. The favourable character of these wounds seems owing to the greater vascularity of the scalp as compared with the common integument; the unfavourable character alluded to seems to be of constitutional origin, erysipelas of the scalp occurring only or chiefly in persons of “broken” constitutional health.

*Treatment* is the same as that of wounds in general; but the circumstances referred to encourage the attempt to solicit union of the scalp, even when extensively incised or lacerated, and detached; and yet render doubtful the issue of even the slightest scalp-wound. The integument should be shaved, and cleansed of any hair, grit, or other foreign body; then laid down and replaced, if detached, and the lips of the wound neatly brought together; strips of adhesive or isinglass plaster being used to retain them in position, aided, if necessary, by a suture here and there. Water-dressing is applied, by a strip of lint, to any part that cannot fairly be drawn together. A bandage may be requisite, but it should be applied as lightly as possible, consistent with its use. Ligatures are not included in this simple plan of treatment, for they are seldom necessary. In the event of *suppuration*, bagging must be prevented by giving a free vent to the matter, from the wound or by an early counter-opening in the most dependent part, and by means of compresses properly applied. With erysipelas or diffuse cellulitis supervening, incisions will be more especially requisite, both to relieve tension and

to discharge matter and sloughs. Exposure of the *bone* is not necessarily followed by exfoliation, or any occasion, therefore, for further interference, to remove dead bone; granulations freely springing up around, and in islets which coalesce, and overspread the bone, the wound heals by this process. Water-dressing or a stimulating lotion, according to the state of the granulations, must be continued as usual, until cicatrization is complete.

Medicinal treatment consists in moderating the circulation by gentle aperients, with a restricted diet. Rest has an important influence, as favouring the process of reparation, and is of the utmost consequence with regard to the liability of cerebral symptoms.

**CONTUSION.**—Without wound, of the scalp, presents the usual characters of such lesion; but the blood-tumour forming, varies with the situation of extravasation, and the localized state of the blood.

Extravasation may occur in three situations; (1) between the skin and the tendinous expansion of the occipito-frontalis muscle; (2) in the loose cellular texture under this muscle; or, (3) beneath the periosteum or pericranium. In either situation, the blood may be infiltrated, or circumscribed more or less in a cavity.

Infiltrated in the dense cellular tissue between the skin and occipito-frontalis muscle, the blood presents a hard unyielding lump; beneath the muscle, it spreads through the loose cellular texture, and gives a crackling sensation when pressed with the finger. Circumscribed extravasation is apt to form a prominent tumour with a soft centre and a hard base, resembling fracture of the skull with depression; for which injury the blood-tumour resulting from contusion may be mistaken, and the more readily if the swelling in connexion with a lacerated artery, pulsates.

The *Treatment* is in no way peculiar. Absorption often taking place, it may be promoted by cold evaporating lotions which check further effusion. Persistent and increasing extravasation justifies evacuation of the fluid, as recommended by Mr. Prescott Hewett. This should be done by a small puncture, after which compression is made and continued over the whole swelling. In large collections, these puncturings may have to be repeated several times; and in an encysted collection of large size, if the fluid has become of a serous character, and recurs again and again, an iodine-injection might be thrown into the pouch.

Suppuration occurring; the bag must, as usual, be laid freely open.

**CEPHALHÆMATOMA**, or blood-tumour of the scalp, forms sometimes, in newly-born children; in consequence of pressure during parturition, or in delivery by obstetric forceps.

The pathology of a blood-tumour thus produced, is much the same as of that arising from an ordinary contusion of the scalp; the blood collecting beneath the tendinous aponeurosis of the occipito-frontalis muscle, or beneath the pericranium. The characters of the tumour are also similar. The treatment must be conducted in like manner. In the only case I have seen, a cephalhæmatoma, of rather large size, over the right parietal bone; time and compression led to a subsidence of the tumour and its gradual disappearance.

**INJURIES OF THE CRANIUM.**—**CONTUSION OF THE BONE.**—Cranial contusion is produced by, and accompanied with, a wound or contusion of the scalp; but it is unconnected with fracture, as being simply a contusion of the bone. Yet the consequences may be very serious or fatal.

*Consequences.*—(1) It may lead to *caries* or *necrosis* of the bone,

affecting one or both tables of the osseous substance; and limited to the seat of injury, or spreading far and wide, even over the whole vault of the skull. In a case related by Saviard, after a blow on the head, the whole skull-cap came away bodily.

(2) *Inflammation of the diploe* is another consequence to be dreaded; such inflammation extending probably inwards to the dura mater, with detachment of that membrane and suppuration between it and the cranium. Thus far the mischief is circumscribed; but the inflammation deepening to the arachnoid membrane, it spreads over the parietal layer, and soon involves the visceral layer; thence the pia mater and corresponding surface of the brain. All the membranes, and the brain, are affected. The periosteum also spontaneously separates; the bone, if denuded, becomes dry and discoloured, and the wound, if there be one, loses its healthy appearance.

The symptoms are insidious and supervene at a variable period, perhaps a fortnight or more after the contusion. The earliest local change is in the appearance of the wound, and the bone if exposed. This is accompanied with pain in the head and feverishness; followed, as suppuration ensues, by sickness, drowsiness, occasional wandering, coma, or paralysis, and death.

(3) *Pyæmia* is apt to arise—possibly, from a simple wound of the scalp, as a third consequence of contusion of the cranial bones. It may occur in two ways; commonly in connexion with intra-cranial suppuration; sometimes, with suppuration of the diploe, the membranes of the brain remaining unaffected, and the veins of the diploe being apparently the source of purulent infection. Its accession is marked by rigors, greatly increased rapidity of pulse, and prostration.

It is very important to bear in mind these three consequences of otherwise *slight* injuries of the head:—death of the bone; inflammation of the diploe, and its associated inflammation of the membranes of the brain, with intra-cranial suppuration; and pyæmic infection.

The *Treatment* of Contusion affecting the Cranial Bones will be given in conjunction with Traumatic Inflammation of the Membranes of the Brain.

FRACTURES OF THE CRANIUM.—These fractures are so intimately related, as causes, to Injuries of the Brain, that they are here considered.

(1) FRACTURES OF THE VAULT OF THE SKULL.—*Structural conditions.*—

Fracture of any part of the vault may be: (a) *Simple Fissure*, or a Comminution of the bone; the former is generally not limited to the seat of injury, sometimes spreading through various bones, and often extending from the Vault into the Base of the Skull; the latter, or *Comminuted Fracture*, is commonly more limited to the seat of injury. *Fissured* and *Comminuted Fracture* may co-exist, and especially when caused by a heavy blow acting on a large surface. *Incomplete Fracture*—

FIG. 319.

*i.e.*, limited to the external, or internal, table (Fig. 319) *alone*, may occur, but comparatively rarely.

(b) *Depressed fracture*; the displacement of the bone being *inwards* (Fig. 320), or *outwards*,—very rarely. Either form of depressed fracture may be *Comminuted*; and the former, or inward depressed fracture, may be a *Punctured fracture*, when it is necessarily comminuted, spicular portions of the internal table being driven in. Traumatic depression of the skull, *without fracture*, is not authenticated by any specimen. In the adult, the existence of such injury cannot be acknowledged; and in children, with pliant bones, some of the bony fibres must be broken.

FIG. 320.

Displacement *inwards* may affect the external, or internal, table alone. The *external table*, Mr. Prescott Hewett observes, may be driven down in any part of the vault, but especially in the region of the frontal sinuses, where the depression may be very extensive, without any injury of the inner table. The *inner table* may be broken and depressed, without a trace of injury about the outer parts of the bone. Such cases are very rarely met with; but extensive splintering and depression of the inner table not unfrequently exist, with some slight injury of the outer table. Fracture of the inner table is always much more extensive than that of the outer table.

Displacement *outwards* may affect the external table only partially. Of such displacement, there are two specimens in the Museum of St. George's Hospital. In both, a piece involving the whole thickness of the bone, having been detached on three sides, is bent outwards, and thus raised two or three lines above the level of the skull; the fragment is immovable, it being still connected at one side to the surrounding bone, the external table of which, at this part, is only partially fractured; the appearances may, in fact, be said to resemble the lid of a box partly open. In one instance, the injury was produced by a chisel falling from a great height on to the head; and in the other, the patient, in a fall from a great height, struck his head upon some iron railings, one of which penetrated his skull.

(c) *Compound fracture*.—A wound of the integument leading down to the bone, may accompany every variety of fracture of the vault. And, the injury of the bone is very much more frequently strictly limited to the seat of the blow than in simple fracture.

*Symptoms, and Diagnosis*.—*Simple fracture*, in any form, is not accompanied by symptoms or signs, invariably, and exclusively, indicative of this kind of injury. *Fissure* may exist, undiscovered during life; and a comminuted fracture with great depression of the fragments, may be concealed by the temporal muscle, or by a large extravasation of blood. On the other hand, either a circumscribed extravasation of blood, or an abnormal depression of the bone, is apt to resemble fracture with depres-

sion. Extravasation into the cellular texture beneath the scalp, raises it, excepting at the part compressed by the contusion. The surrounding swelling thus produced is very firm, and its central margin resembles that of fracture, with depression. Beneath the muscle, extravasation spreads, and yields a crackling sensation on gentle pressure. An abnormal depression of the skull is congenital; or slowly produced by absorption of the diploe and attenuation of the tables, as sometimes occurs in advancing years.

*Depressed fracture* is accompanied by the symptoms of *Compression* of the brain; namely, more or less complete suspension of the cerebral functions of consciousness, sensation, and voluntary motion. The same symptoms may proceed from extravasation of blood, or from the formation of purulent matter, under the cranium. But, with depression, these symptoms are immediate; with extravasation, there was an *interval*, during which consciousness may have been regained more or less completely, as Concussion passed off;—symptoms of compression supervene, and gradually increase with further extravasation; with pus-formation, there was also an interval, during which *inflammatory* symptoms were present, those of compression supervening.

*Compound fracture* may be detected; care being taken not to mistake any natural suture or vascular groove for fracture-fissure. Any abnormal disposition of a suture is especially misleading.

*Causes, and their Effects.*—*Direct violence* is almost invariably the *only* cause of fractures of the cranium in its vault, an etiological distinction as compared with fractures of the base. Falls on the head, and blows with almost every kind of weapon, are the occasions of direct violence. Suicide is sometimes effected by firing a pistol into the mouth. I have seen one such instance; the ball penetrating the base of the skull, and passing through the brain, struck the vertex of the skull; fracturing the inner table, and raising the outer, it fell back into the substance of the brain.

The effects of this mode of fracture are various. In addition to *wound* of the scalp, occipito-frontalis muscle, and pericranium or periosteum; *extravasation* of blood may occur beneath either of these integuments—parts external to the vault of the cranium. Thus, extra-cranial extravasation is found in one, or more, of three situations; between the scalp and the tendon of the occipito-frontalis muscle, between that muscle and the pericranium, or between that membrane and the bone. The *skull*, *brain* and its *membranes*, may be severally and similarly involved, as extensions of the fracture-injury to the contents of the cranial cavity. These effects are produced, principally, by depressed fracture. They are separation of the dura mater from the interior of the cranium, wound of this membrane, of the arachnoid, pia mater, and laceration of the brain; extravasation of blood in the diploe of the skull, or between the bone and dura mater; or into the cavity of the arachnoid; or beneath the arachnoid and in the pia mater; or into the substance, and ventricles of the brain. No certain relation exists between these effects and the extent of depression. Hence also the want of any certain correspondence between the symptoms of compression and the depression; those symptoms being slight perhaps, with considerable depression, and severe with slight depression.

The *source* of hæmorrhage varies. Extravasation between the bone and dura mater may proceed from the small vessels passing from one to the other, or from some of the large vessels lodged in the grooves on the

inner surface of the skull. The former extravasations—observes Mr. Hewett—are, generally, of small size; but the latter may be very extensive, widely separating the membrane from the bone over the greater part of one side of the skull. The middle meningeal artery is the source of these large extravasations, in the majority of cases. It was so in 27, out of 31 cases. One of the large venous sinuses may be the source of extravasation, and the lateral sinus more commonly than any other sinus. The situation of extravasation from the middle meningeal artery, is usually regarded as the anterior inferior angle of the parietal bone; but extensive extravasations may occur from this vessel, or some of its branches, over nearly the whole of the lateral surface of the skull. So also, with fracture of the base of the skull, extravasations from this source are common.

*Intra-cranial extravasation* is attended with *Compression* of the brain; denoted by more or less complete suspension of the cerebral functions of consciousness, sensation, and voluntary motion. But—unlike the immediate compression by depressed fracture—these symptoms supervene after an interval, however short; during which consciousness may have been, more or less completely, regained.

*Consequences.*—(1) *Extravasated blood* remains infiltrated, or becomes encysted and undergoes changes of spissitude and colour. In either of the three situations of extra-cranial extravasation; the primary condition, or this alteration, may be found. But with intra-cranial extravasation; blood effused between the dura mater and bone, or in the pia mater, never seems to become encysted; while in the cavity of the arachnoid, it is liable, even prone, to acquire a perfect cyst, if the extravasation be large, or to form tough membranes; such cyst or membrane becoming provided with blood-vessels. These changes are, however, the work of time.

(2) *Inflammation*, with lymph and pus-formation, within the cranium, is always liable to supervene, in consequence of fracture, and in the same situations as intra-cranial extravasation may occur; namely, in the diploe of the skull, between the bone and dura mater, in the cavity of the arachnoid, beneath the arachnoid and in the pia mater, and in the substance of the brain.

Symptoms of inflammation affecting the bone, the membranes, or the brain; are followed by symptoms of *Compression*, as lymph and pus-formation supervene. But—as with extravasation—an interval of time elapses between the fracture and *these* symptoms; an interval of longer duration, usually several days, during which, however, inflammatory symptoms prevail, instead of consciousness returning.

(3) *Pyæmia*, consequent on fracture of the skull, is mostly connected with inflammation and suppuration of the diploe, implicating some of the numerous and large venous sinuses in the bone.

*TREATMENT.*—The question of operative interference turns principally, on the presence, or absence, of *Compression*-symptoms; and partly, on the presence, or absence, of *Compound-fracture*—a wound already leading to the seat of fracture.

The rules of treatment, accordingly, are thus expressed by Mr. Hewett:—

*Linear fracture or fissure*, unaccompanied by brain-symptoms, even although compound, is not to be interfered with; the wound must be treated according to circumstances, and the case carefully watched for some time.

*Comminuted* fracture, even with depression of the fragments, but unaccompanied with symptoms and a wound, should not be interfered with. It is now an established rule in our Metropolitan Hospitals, that *Simple* fractures, with depression but without symptoms, are to be left alone. The depression may be so marked as to be easily detected; but so long as there are no symptoms, all operative interference, of whatsoever kind, should carefully be avoided.

*Compound* fracture, with depression, although without symptoms, justifies operative interference, and immediately. This rule was inculcated by Sir A. Cooper, and Sir B. Brodie, to prevent intra-cranial suppuration consequent on this condition of fracture. The former authority observes:—"The elevation of the bone is never followed by any mischief; but if you do not raise it, and inflammation follows, it will then be too late to attempt to save the life of the patient." On the other hand, the *presence* of symptoms in this condition of fracture, alone justifies operative interference, in the experience of the late Sir Philip Crampton. "In Dublin"—he remarks—"we conform generally to the rule originally laid down by Dease, who preceded Desault by many years; that, in fracture of the skull with depressed bone, whether complicated by *wound* of the scalp or otherwise, no attempt should be made to raise the depressed bone, unless very decided symptoms be present of compressed or irritated brain."

*Punctured* fracture—sharp splinters of the inner table being driven in, albeit without symptoms—most imperatively demands operative interference.

But, certain *exceptional conditions* of ordinary compound fracture may be noticed. A slight depression, especially when it corresponds to the thicker part of the injured bone, does not require an immediate operation. A deep driving-in of the bone over the frontal sinuses, is another exception; always remembering that these sinuses do not begin to form until several years after birth. A compound fracture with depression, but without symptoms of inflammation, some days after the accident; will justify non-interference, and the more so, if the depression is broad, and the fracture comminuted. Such a condition may proceed to recovery without any intra-cranial inflammation. Thus far, respecting fractures, of the skull *without* brain symptoms, in regard to their rules of treatment.

*Depressed* fractures, accompanied *with* primary brain symptoms.—*Simple* fracture with the symptoms not very urgent, justifies postponement of operative interference; but with urgent symptoms, it demands such interference.

*Compound* fracture, depressed, with symptoms; also demands interference, and immediately. It may, or may not, prove successful, according to the urgency of the symptoms, depending on the fracture-depression.

In childhood, a depressed piece of bone remaining, does not generally produce the serious results, which are commonly noticed in the adult. Postponement of elevation or trephining, is, therefore, allowable; when, in an adult, the operation should be performed at once.

(2) FRACTURE OF THE BASE OF THE SKULL.—*Structural Conditions*.—Commonly a fissured or radiated fracture; there is little or no displacement, the bones being nearly immovable. The fracture may be situated in either the middle, posterior, or anterior fossa of the base, and generally in this order of occurrence—the fissure passing through the petrous por-

tion of the temporal bone, or into the foramen magnum. Two fossæ may be implicated; as the middle and posterior, in 15 cases out of 29; or the middle and anterior, in the remaining 14 cases. All three fossæ may be implicated concurrently; but this happened in only 10 cases in 10 years.

*Symptoms, and Diagnosis.*—The only peculiar and reliable symptoms, of fracture of the base, are; the escape of some of the contents of the skull—*blood*, through the ears, nose, or into the orbit; a *serous fluid*, probably the cerebro-spinal fluid, from the ears, or nose; or *brain-substance* possibly, accompanied with special symptoms of injury to the cranial nerves as they emerge from the skull.

But all these symptoms vary with the *situation* of the fracture.

In the *middle fossa*, there is probably fracture of the petrous portion of the temporal bone, with rupture of the tympanum; and thence the escape of watery fluid, or blood, from the ear. A copious discharge of watery fluid from the ear, immediately after the accident, leaves no doubt that such is the nature of the injury. A copious and prolonged bleeding from the ear, followed by a watery discharge, also indicates the same injury—fracture of the petrous bone. A discharge of blood, neither copious nor prolonged, followed by watery discharge, varying in the time of its appearance and its quantity; renders the diagnosis doubtful. The discharge of blood is—according to recent experience, Mr. Hewett affirms—certainly not of a character to warrant the diagnosis of fracture of the petrous bone; while, a watery discharge may occur a few hours after the accident, and may even be profuse in quantity, and yet there be no fracture. In the *posterior fossa*, fracture is more obscure; unless it extend into the petrous bone. In the *anterior fossa*, fracture is attended with extravasation of blood into the orbit, thence under the ocular conjunctiva, and eyelids—the lower one first, in most cases. Hæmorrhage from the nose also, not unfrequently occurs. But fracture in this fossa may exist without any extravasation under the ocular conjunctiva, or with only discoloration of the lids; and then, the fracture however extensive cannot be diagnosed. Extravasation in both these situations may also arise from fracture of the superior maxillary or malar bones.

Fractures of the base are sometimes attended with extravasation of blood into the cellular tissue of the mastoid region, or at the back of the head.

The *source* of the blood in any case is uncertain; the fracture must involve some of the large vascular channels lying at the base, and also open up a way for the escape of blood externally. Either or both these effects not being produced; very extensive fracture may exist, undiscovered during life. In fracture involving the *middle fossa*, the middle meningeal artery may be ruptured in any part of its course between the foramen spinosum and the anterior-inferior angle of the parietal bone.

The blood is either arterial or venous. Thus, fracture in the anterior fossa, involving the orbital plates of the frontal and extending into the sphenoid bone will lay open the venous sinuses, or the ophthalmic artery, there situated; and more commonly the former.

Vomiting of blood occurs, when during hæmorrhage the blood has passed down the pharynx into the stomach.

*Causes, and their Effects.*—*Indirect* violence is almost invariably the *only* cause of fractures of the cranium, in its base. A heavy blow, or fall, on the top of the head, is commonly the cause; but a fall, the

person alighting on his feet, or the buttocks, is an occasional mode of indirect violence. In either case, the cranium is compressed between two forces, the force of collision on the vertex and that of resistance by the apex of the spinal column; or the latter may be driven upwards, and the top of the head downwards, as in the case of a person falling on his feet.

The production of fracture by indirect violence, at the *opposite* part to the part struck, is designated fracture by *contre-coup* or counter-stroke; the cranium yielding laterally, and giving way at the opposite point of resistance or impulsion. And such was long thought to be the mode in which fracture was produced at the base of the skull. But more recent observations, and especially Dr. Aran's experiments, have shown that, generally, these fractures begin, not at the base, but start from the part of the vault struck, and thence stretch round into the base. In the front of the vault, such fracture thus leads to fracture of the anterior fossa; in the middle or vertex of the head, to fracture of the middle fossa; and at the back of the head, to fracture of the posterior fossa; in each situation of fracture, a line leading from the corresponding part of the vault. Fracture of the base of the skull by *contre-coup* would therefore seem to be of very rare occurrence. *Direct* violence is, comparatively, very rarely the cause of fracture in any portion of the base. But, at certain parts, the bones are thin and brittle, readily yielding to any force directly applied. Such are the orbits, the nostrils, and the occipital fossæ. Sharp-pointed instruments, as scissors, or a tobacco-pipe, may penetrate the cranial cavity in these situations, and also injure the brain. The condyle of the lower jaw has even been driven into the middle fossa of the base.

The immediate effect or operation of either indirect or of direct violence is by its extension to the vessels at the base of the brain, to the membranes, and brain, or cranial nerves. Hence, extravasation of blood, the escape of cerebro-spinal fluid, or even of brain-substance, and injury to the nerves emerging from the skull.

*Terminations.*—(1) Fracture of the base,—the more common form of fractures of the skull, is very frequently fatal. (2) In the event of recovery; no union may have taken place, after months or even years; or, union partly by dense fibrous tissue with a thin layer of inlaid bone; or, bony union, and throughout the whole line of fracture. In some of the latter cases, porous bone has been found heaped up along the sides of the line of fracture, on the inner aspect of the skull, and even blocking up one of the venous sinuses.

*Treatment.*—No operative interference is requisite, or practicable, in fracture of the base. Itself remaining without displacement, the brain-lesions alone assume the whole consequence of the injury. Trephining has, however, been performed successfully, close to the foramen magnum.

**INJURIES OF THE MEMBRANES OF THE BRAIN.**—*Extravasation of Blood within the Cranium.*—Intra-cranial extravasation, in connexion with Injury of the Head, may occur with, or without, Fracture of the Skull. But the pathology of extravasation, thus arising, is the same;—with regard to the situations of effusion, the symptoms, and consequences. These have been already described.

The *Treatment* is that of Compression.

**HERNIA CEREBRI.**—Protrusion of the brain-substance is liable to occur in connexion with laceration of the brain and its membranes, communicating with compound fracture of the skull. The projecting portion of

brain not having any integumental covering is not properly speaking a hernia, and is sometimes designated *fungus cerebri*. It may present itself in any part of the skull; but commonly in some part of the vault, and especially the frontal and parietal regions. It rarely occurs at the base of the skull; brain-substance then being forced through the ear, nose, or possibly into the pharynx.

The appearances are those of brain-substance, more or less modified; as having a brown colour and bloody character. Nerve-tubules, with the products of inflammation, may be discovered under the microscope. The more obvious appearances as well as the microscopic characters, will therefore distinguish brain-substance either from a collection of blood protruding under the pia mater, or exuberant granulations from the brain. And, moreover, *hernia cerebri* is continuous with the brain.

The causes of *hernia cerebri* would seem to be, the loss of a portion of bone,—hence rare in fracture of the base—and compression of the brain, resulting from inflammation with the effusion of lymph and pus. The surrounding portion of brain becomes congested, and undergoes yellow softening and disintegration, abscesses form in the hemisphere, and effusion distends the ventricles. The products of inflammation occupy also the cavity of the arachnoid and the sub-arachnoid tissue. Protrusion may occur as the immediate consequence of fracture, but more frequently, at a subsequent period,—days or weeks afterwards, when inflammation is established. The symptoms then, are those of inflammation of the brain and its membranes, and such as may exist without any protrusion.

The course, and terminations of *hernia cerebri* are peculiar. Varying in size and shape, according to the aperture in the dura mater through which it had to pass, the tumour gradually increases in bulk, even forming a large mass overlapping and concealing the wound in the scalp; daily breaking down and sloughing, the tumour is constantly reproduced by further protrusion. Few symptoms, perhaps, of cerebral disturbance accompany this course of destruction, but at length death ensues, as the usual issue. Occasionally the tumour sloughing, or shrinking, it wastes away, and cicatrization of the wound follows; the patient recovering without any apparent impairment of his brain-power. This has occurred after a very large protrusion; in one remarkable case, published by Mr. Spring, in the Lond. and Edin. Month. Journ., 1844, the patient lived eleven years, and after death, the left side of the cranium is said to have been found quite empty.

*Treatment.*—As a general rule, *hernia cerebri* should not be interfered with; and no removal of the tumour is allowable, whether by slicing it off, or by ligature. Cleanliness by gentle syringing with cold water, and water-dressing; may be assisted by slight pressure, when the protrusion is small. Any splinter or depressed fragment of bone, or other foreign body, should be extracted, when accessible without undue risk; and particular care must be taken in such operation, not to injure the dura mater.

**INJURIES OF THE BRAIN.—CONCUSSION.**—Literally signifying a shaking, more or less severely; this also is the pathological meaning of the term concussion. Concussion of the brain is a shaking of the brain.

(1) No lesion of the brain may be discovered after death; and it was formerly held, or it is perhaps still maintained by some Surgeons of authority, that concussion may prove fatal immediately, without a trace of injury to, or in, the brain-substance. But of late years, this doctrine

has been disproved by more careful post-mortem examinations. It is now held by several pathologists who have specially investigated cerebral affections; that, in concussion, instantaneously fatal, appreciable lesions are to be found in the brain. These lesions may be various; points of extravasated blood, numerously scattered, or circumscribed patches of contusion or bruising; on, or in, the brain-substance. Such is the pathology of concussion of the brain, as shown by Chassaignac, Nélaton, Sanson, Dr. Bright, Blandin, M. Fano, and enforced by the observations of Mr. Prescott Hewett.

(2) In concussion, not immediately fatal, where life continues for a short time or a few hours, another result is found;—intense congestion of the cerebral vessels and permeating the whole brain-substance; without perhaps any actual lesion.

(3) Slight concussion, followed by recovery, is probably connected with similar injury to the brain and congestion; varying only in degree, but having no definite proportion to the previous symptoms of concussion. This state of disorganization of the brain is sometimes verified by post-mortem examination, after slight concussion, when death has occurred from some other injury. Mr. Hewett describes two such cases.

These are the only essential lesions in concussion of the brain, as authenticated by more recent observations. The question, in both a positive and negative sense, is obviously of much importance Surgically, and no less so from a Medico-legal point of view.

*Symptoms.*—The symptoms of concussion of the brain are, essentially, loss of *consciousness*—comprising a suspension of all the functions of the brain, as the direct and immediate effect of the injury. The person is stunned. Three degrees of this state are now commonly recognised—(1) *Slight* concussion; with momentary loss of sensibility and of muscular power; and with depression of the circulation, as denoted by a feeble pulse at the wrist. These symptoms soon pass off; the person comes to again, and proceeds about his business as if nothing had happened, retaining, often, no knowledge of the injury. (2) *Complete* insensibility; the patient lying motionless, pallid, and cold, the pulse scarcely perceptible. The pupils of the eyes vary very much, being contracted or dilated; or one contracted and the other dilated. The breathing is feeble, but, in the majority of cases, easy. The urine and fæces are sometimes voided involuntarily. This state having continued for a period of longer or shorter duration, imperfect sensibility returns; the patient can be roused to answer a question with bewilderment of manner, and then relapses; vomiting supervenes as a symptom of recovery, and the symptoms of concussion gradually pass off in a few hours or days. Head-ache, confusion, and giddiness remain, or symptoms of intra-cranial inflammation supervene. (3) *Complete* insensibility, and the *pulse imperceptible*. No reaction ensues, and death takes place in a few minutes or a few hours.

The *diagnosis* of concussion and compression of the brain, will be considered in connexion with the latter state.

The *cause* of cerebral concussion is, of course, external violence, applied directly to the head as by a blow or fall; or indirectly, by transmission through some other part of the body, as when a person falling from a height alights on his feet.

*Consequences.*—*Inflammation* of the brain, or its membranes, is always liable to ensue, even from slight concussion, and after an interval of apparent health. The approach of inflammation may be very insidious, and its

results permanent, in the impairment or loss of various cerebral functions. Thus, the memory fails with regard to places or persons, dates, or the recollection of certain words. The special senses become impaired, as by loss of sight, with paralytic falling of the upper eyelid,—ptosis, or squinting; and one or both eyes may be affected. Loss of hearing is sometimes experienced, or various disturbing sounds in the head are heard, and smell or taste may be perverted. Sleeplessness or horrible dreams complete the misery of these purely-cerebral affections, and paroxysms of maniacal excitement are apt to be induced by any slight indulgence in drink, or by any other occasion of cerebral influence. The muscular strength declines, and the sexual power becomes impaired; while the general health, as depending on innervation, is reduced, and the patient brought to a cachectic, broken, state, the very shadow of his former self. Strange to say, the pulse may remain unaffected, or remarkably slow, as if not indicative of any inflammatory mischief in the brain; and this seems to be more particularly observed when the base of the brain is the seat of such morbid change as declared by the character of the functional symptoms. These results I have had the opportunity of witnessing in several cases, consequent on concussion by railway injury, in which I have been engaged; but it is to be regretted that, in some such cases, their issues cannot be ascertained.

*Treatment.*—The pathology of concussion supplies two general indications of treatment; to prevent increasing congestion or the tendency to inflammation, and to give time for the cerebral lesions to recover themselves. Hence, in the *stage of depression*, or insensibility, interference should be little, and judicious; on the one hand, not to increase congestion by blood-letting or other reducing measures, on the other hand, not to hurry on reaction and the tendency to inflammation, by over-stimulation. Stimulants should be administered in proportion to the depression and its continuance, as evinced by the state of the circulation and pulse. But it should be remembered, that while slight depression will be followed by slight reaction, extreme depression will be succeeded by extreme reaction, and this, therefore, would be aggravated by over-stimulation previously. In the stage of *reaction*, interference should be regulated by its degree, as bordering on inflammation. An elevated position, with cold lotion, to the head, shaved for its application, are the best safeguards. A reduced diet and abstinence from stimulants, coupled with the administration of gentle, watery, aperients, will effectually keep the circulation in check. Any tendency to relapse must be watched at the same time, and prevented by recurrence to stimulating treatment.

Absolute rest, and the withdrawal of all surrounding circumstances of excitement, are imperatively necessary to recovery. A quiet life should then be led, for some time; and, if possible, the patient continue under medical supervision. It was justly remarked by Liston, that no injury of the head is too trivial to be despised, or too serious to be despaired of.

Intra-cranial Inflammation, and its consequences, as arising from Concussion, will be considered under the general heading of Traumatic Inflammation of the Brain.

**CONTUSION OF THE BRAIN.**—Bruising and laceration of the brain-substance is associated with concussion, but it may be the most prominent form of lesion. Consisting of spots of extravasated blood and disintegrated brain-substance; these are commonly clustered together in well-marked, circumscribed patches, or occasionally scattered and diffused

throughout various parts of the cerebral mass. In the one form of contusion, the grey substance alone is affected, in other form, the white substance also.

The *situation* of contusion may be either at the spot where the skull was struck—direct contusion, or distant from the seat of violence—contusion by contre-coup. The middle and anterior lobes, and especially their under-surface, are more frequently bruised than the posterior lobes.

The *symptoms* are, unconsciousness more or less complete, without stertorous breathing; tonic spasms of the limbs, and a restless rolling and tossing about in bed. But these symptoms are not immediate, and therefore not necessarily dependent on contusion. This kind of lesion has no symptoms of its own. They have been said to denote cerebral irritation, as a primary form of cerebral disturbance, arising from injury. But the symptoms are not only of subsequent origin, they are also not peculiar. I have seen precisely the same symptoms connected with an abscess in the right posterior lobe of the brain.

**COMPRESSION OF THE BRAIN.—Symptoms.**—The symptoms of this condition, when fully established, are; insensibility, or coma, as of a profound sleep; the breathing is laborious, slow, and prolonged, accompanied with a stertorous or snoring noise, owing apparently to paralysis of the velum palati, and a puffing blowing of the lips; this sound dying away now and then, it may be succeeded by a sort of catch in the throat, with a start, and relapse into deep snoring; the pupils are dilated, and the pulse is slow and full. The *fæces* may pass involuntarily, and the urine be retained, or dribble away. This general state is sometimes varied by attacks of delirium or convulsions.

*Diagnosis.*—The distinction between compression and concussion has been generally determined—mainly by the three symptoms, of the breathing, the state of the pupils, and the pulse; as already described with reference to each of these conditions of the brain. In typical, or well-marked representations of either condition, it will be possible thus to decide the question of their diagnosis. Much stress has, therefore, been laid on the aforesaid distinctive characters. But in intervening states of cerebral injury, the diagnosis is equivocal. Mr. Hewett affirms that “there is no one symptom, or combination of symptoms, which will enable us to determine positively between concussion and the slighter cases of compression.”

The *causes* of compression agree in their general nature; they are all some source of pressure on the brain; they vary in being—a depressed portion of bone, a depressed fracture, or other impacted foreign body, extravasated blood, or a collection of matter, within the cranium; and thus these causes differ widely in their pathological origin and significance. Two such causes may co-exist, as depressed fracture, with extravasation of blood; or all may co-exist, as intra-cranial suppuration, with depressed fracture, and extravasation.

*Consequences.*—*Inflammation* of the brain, or its membranes, is equally liable to ensue as from concussion, although the cause of compression will affect the probability of this event. Depressed fracture inevitably leads to inflammation, and intra-cranial suppuration presupposes it. Death results from continued compression, in a period varying with the degree of pressure, and the functional importance of the part of the brain affected.

A stationary condition of compression remains occasionally; the patient lying comatose for weeks, or months, and recovering consciousness when

the compressing cause is removed. A most remarkable case of this result is recorded by Sir A. Cooper, that of a man whose cerebral functions were entirely suspended for a period of thirteen months, by a fall on his head from the yard-arm of a vessel, producing a depressed fracture; but, on trephining the bone, and thus removing the cause of compression, consciousness returned immediately after this long period of total oblivion—for more than a year.

*Treatment.*—Obviously, the compressing cause must be removed. This implies a different mode of proceeding according to the particular cause in operation.

The head should be shaved and carefully examined. (1) *Depressed fracture* will probably necessitate the elevation of the depressed portion of bone, by means of an elevator, or its removal, by trephining. The conditions which justify these operations have been already enumerated in the rules of Treatment pertaining to Fractures of the Cranium. The question of removing a foreign body, as the cause of pressure, may be determined by the same code of rules. (2) *Intra-cranial extravasation of blood*, can, generally, be treated without recourse to operative interference. The compressing cause is the same as that of apoplexy. Hence the extravasation of blood may be arrested and reduced, by cold applications to the head, and by the depletory action of purgatives. No form of purgative seems to act so speedily and impressively on the brain, as a turpentine enema; say, an ounce of turpentine to a pint of gruel, the strength which I am in the habit of ordering. Its beneficial influence should be aided by bottles of hot water to the feet, and similar means of derivation from the brain. It would be highly important to know, whether a more powerfully derivative action could be established, by means of the suction-apparatus applied to either of the lower limbs; such as was, I believe, originally employed, under other circumstances by Mr. Jobert. (3) *Intra-cranial suppuration*, is always a question of considerable difficulty, as to its existence and situation. This will be considered, and the necessity of having recourse to the operation of trephining, in describing Traumatic Inflammation of the Membranes of the Brain.

WOUNDS OF THE BRAIN, arise from Fracture of the skull, or the simultaneous penetration of some instrument, or other foreign body. Such lesions, therefore, scarcely require a separate notice.

But the *symptomatic effects* differ from those of concussion and compression. A great part of the brain of an animal—observes Mayo—may be gently and quietly sliced away with little or no effect, but if ever so small a portion be suddenly crushed, the heart stops directly. Thus also with regard to wounds of the human brain; Cole, in his “Field Practice in India,” narrates certain apposite facts.—“The English dragoon sword is so blunt, that the strongest man cannot drive it through the head-dress of the Sikh or Afghan; yet, the enemy is most often beaten from his horse, and frequently killed by the violence of the shock. Not so, however, with the trenchant blade of the Sikh; this weapon, wielded by a strong man, will cut through any head-piece, and bury itself perhaps in the brain, and yet you find no symptoms of concussion or compression. In the former example, the soldier is effectually disabled, often killed outright; in the latter, although the individual is mortally wounded, he may be able to continue the fight, and even to kill his antagonist, before he falls himself, dead or dying from his horse.”

INJURIES OF THE CRANIAL NERVES.—In connexion with injury of the

Brain or its Membranes, one or more of the cerebral nerves are sometimes involved, and their functions impaired.

The *causes* of such injuries and functional impairment, are various, and the same as those of Brain-injury. Thus, one or more of the cerebral nerves may be injured by an *instrument* producing fracture. This mode of lesion, a rather rare occurrence, is more liable to happen to certain of these nerves, owing to their more accessible situation; the optic and olfactory nerves being especially liable to be injured by a thrust-wound. The *fracture* itself may implicate one or more of the foramina or canals, through which some of the cerebral nerves emerge from the base of the skull. Certain nerves are more frequently thus injured than others, owing to the relative frequency of fracture in these situations. The seventh nerve, on account of the frequency of fracture through the petrous portion of the temporal bone, is often injured in this manner; paralysis of the facial or auditory nerve generally denoting fracture of the base of the skull. A portion of broken bone, distant from the foramen or canal of transmission, sometimes occasions injury to a nerve with which it is connected. *Extravasation* of blood at the base of the brain may affect a cerebral nerve, by pressure on the brain at the origin of the nerve, or on the nerve in some part of its course. This mode of paralysis is more temporary; absorption proceeding, it gradually disappears.

The *Treatment* of these implications of the cerebral nerves, is chiefly negative. The natural process of reparation after any such injury and the restoration of function, will probably prove more effectual, than any blind interference. If the lesion depend on extravasated blood, we know too little of the remedial efficacy of mercurials and blistering for promoting absorption, or of nerve-tonics, for restoring nerve-function, to regard these measures with much confidence.

TRAUMATIC INFLAMMATION OF THE BRAIN, AND ITS MEMBRANES.—Pathologically considered, Inflammation may affect the Brain or its Membranes, separately; and when of traumatic origin, it may be appropriately named Traumatic Encephalitis and Traumatic Meningitis, respectively. Practically considered, however, these affections are identical, the one giving rise to the other; and both may be described as Inflammation of the Brain.

*Symptoms.*—The symptoms of traumatic intra-cranial inflammation are principally these;—pain in the head, more or less intense, limited to the seat of injury, or spreading thence over the whole head, contraction of the pupils, intolerance of light and sound, with general feverishness as denoted by a rapid pulse and hot, dry, skin.

These symptoms, becoming more marked, are succeeded by special disturbance of the brain-functions;—delirium or wandering, sickness, restless tossing about, and perhaps convulsions. The aspect of the patient is, indeed, sufficiently characteristic—the excitement and agitation, wild glistening eyes, flushed face and throbbing carotids, all indicate the state of the cerebral circulation.

The *second stage* contrasts very much with that of excitement. Drowsiness, stupor and coma, with dilatation of the pupils, spasmodic twitchings of the muscles, paralysis, and relaxation of the sphincters; indicate effusion, and compression of the brain. Rigors, announce supuration.

The structural alterations or appearances resulting from inflammation of the brain, and membranes, vary according to the seat and progress of

the inflammation. They may be summarily enumerated as follow:—suppuration in the diploe; lymph or pus of a greenish yellow colour, circumscribed on the outer or cranial surface of the dura mater between it and the bone, and diffused beneath this membrane within the cavity of the arachnoid, and on the pia mater filling its meshes and prolongations between the convolutions; so that the membrane thus thickened can be removed as a whole from the brain and looks as if it had been cast in wax. Softening of the brain-substance, abscess in the central part of the brain or cerebellum, and effusion of serum in the ventricles; constitute the alterations peculiar to the brain. The veins are more or less engorged with blood, and the venous sinuses contain coagula.

All these appearances however may not co-exist in any one brain, as the results of inflammation.

The *causes* of intra-cranial inflammation, consequent on injury of the head, are the various conditions of injury already described. Thus, scalp-wound, and contusion of the cranium; fractures of the skull, with injury of the membranes of the brain; concussion, contusion, compression, and wounds of the brain; these several forms of lesion are the starting points of inflammation.

The train of symptoms above mentioned, supervene at a variable *period* after injury of the head; and this question of time has a tolerably definite relation to the cause of inflammation, thereby indicating the probable source of the symptoms. If dependent upon concussion, the symptoms of intra-cranial inflammation appear at a very early period—perhaps within a few hours; as arising from contusion of the brain-substance, they generally supervene about the fourth or fifth day; whereas from contusion of the bone, the inflammatory mischief may smoulder for a time—many days, or two or three weeks, and then suddenly burst forth.

The *prognosis* of intra-cranial inflammation is always precarious, and especially in the second stage, that of effusion or suppuration with coma.

*Treatment.*—The head should be shaved, and raised in an elevated position; and cold lotions or an ice-bag be applied. Free purgation must then be brought into action, and blood-letting in some form. Local bleeding by means of leeches applied to the temples, or cupping on the nape of the neck, will always be advantageous; general blood-letting may be had recourse to according to the severity of the symptoms, and small repeated bleedings are safer and make a more permanent impression on the cerebral circulation than one large blood-letting. Antimonial salines prove useful adjuncts to these depletory and sedative measures, by continuing their influence on the system. Opium had better not be administered in large or opiate doses; although, in the form of morphia, it may be given to control furious delirium. Calomel, in small doses, combined with opium, should be pushed to salivation. These measures must be followed up by derivation from the head, by blisters applied to the nape of the neck or the head. A blistering-cap is used by the French Surgeons, and dressing the blistered surface with mercury, has sometimes been most effectual for restraining effusion in the second stage of inflammation.

The state of the viscera, and of the kidneys in particular, should always be examined thoroughly—as recommended by Mr. Hewett—in relation to both the diagnosis and treatment of inflammation of the brain, arising, apparently, from any injury of the head.

*Compression* of the brain, indicated by coma, and as depending on *suppuration*, may justify recourse to the operation of trephining. But under what circumstances? Rigors are the surest sign of suppuration. Then, with coma, and especially with hemiplegia, the question is the *situation* of the matter. Scalp-wound injury, or contusion of the bone, will generally indicate the spot. The matter may be located between the bone and dura mater; or *also* beneath this membrane, although very rarely circumscribed within the cavity of the arachnoid,—the dura mater then bulging up tensely into the trephine-aperture, and not presenting any pulsation. An incision must be made and the matter let out.

The operation will, therefore, be effectual in these two *exceptional* conditions—(1) for the evacuation of matter *beneath* the *cranium*, alone; (2) or associated with its *circumscribed* formation *beneath* the *dura mater*, in the cavity of the arachnoid.

(3) Abscess in the *Brain* may be superficial or deep. The difficulty will be to determine this question. Having trephined the skull, in consequence of compression-symptoms, one of two conditions may be found. Matter may at once escape through an opening in the dura mater, that membrane having sloughed over a communicating abscess. The difficulty is solved. But if the membrane be entire, without bulging under the trephine-aperture, and with symptoms still of compression; the question again arises as to the situation of the matter, superficially or deeply in the brain? In this doubtful condition, the dura mater has been divided; yet the patient has died with an abscess then only discovered, situated just below, under the cortical substance of the brain, and thus provokingly close to the trephine-aperture; or again the abscess, so placed, has burst subsequently, and the patient entirely recovered. The one case—that of leaving the brain intact with a fatal result, happened to Roux; the other, that of natural evacuation of the matter ensuing with recovery, happened to J. L. Petit. The fair inference is this—that if an abscess can be reasonably suspected to be situated *superficially*, as shown by the state of the brain at the part exposed, a slight incision into the brain may then be made to discover and evacuate the matter. *Deep*, or central abscess, also, might be interrogated in the same way, and for similar reasons. Dupuytren plunged a knife into the brain, and at once saved the life of his patient; Dr. Detmold also made deep incisions into the brain, on three different occasions in the same case; the first saved the man from impending death; the latter two, touching the left ventricle, seemed to afford the only chance of recovery. But it is not probable that such deep incisions will be repeated by other Surgeons.

OPERATION OF TREPHINING. — The conditions of Head-injury, with compression, which render this operation necessary or judicious, having been already fully considered, the operation itself remains to be described.

The instruments requisite are, a trephine (Fig. 321), small or large-sized, according to the purpose of the

FIG. 321.

operation—either the removal of a portion of bone as the source of compression, or the evacuation of subjacent fluid, extravasated blood, or pus. An elevator, and Hey's saw, are the only other special instruments.

The head is to be shaved around the seat of operation; the bone, if not already exposed by a scalp-wound, must then be laid bare by a crucial, or T-shaped incision. The trephine, with its centre-pin protruding and fixed into the skull, should be worked from left to right, with a firm moving, but light-bearing, action. (Fig. 322.) A fair groove having been thus made, the steadying centre-pin is no longer necessary, and should be withdrawn, lest, passing more deeply, it penetrate the skull first and wound the brain. Complete division of the outer table, and entrance into the diploe, will be plainly shown by the altered character of the *détritus* thrown up by the saw—the dry, white, flour of the hard bone being succeeded by bloody and soft grit. A sensation of yielding in entering and passing through the diploe is also very perceptible. It should be remembered that no diploe will be found either in children or the aged. The instrument must now be worked very lightly and cautiously, and withdrawn every turn or two as it approaches the *dura mater*, in order that the groove may be examined with a probe to ascertain the

FIG. 322.

depth and uniformity of penetration around the circular piece of bone. When it seems loosened, an elevator is gently introduced into the groove, and the portion of bone removed.

The particular object of the operation can now be accomplished. Pus or blood will escape or may be evacuated; or a depressed portion of bone can be raised, by insinuating the elevator beneath it and bearing on the finger or the edge of the firm bone as a fulcrum. This implies that in trephining for fracture, the circular piece of bone removed must communicate with the edge of the depressed portion and afford space for its elevation. Sometimes, a projecting portion of bone can be removed with a Hey's saw, or bone-pliers, and space thus made for the introduction of the elevator, without using the trephine. Certain parts of the skull are also ineligible for trephining—namely, over the occipital bone, in the course of the venous sinuses, and over the frontal sinuses. In the latter situation, however, the outer table may be first removed and then the inner. In any situation, loose fragments or *débris* of bone must be carefully picked or brushed out, and the wound gently sponged clean; the scalp is then laid down, retained with a few sutures, if necessary, and a strip of water-dressing applied.

The *after-treatment* consists entirely in measures preventive or curative of inflammation and its consequences.

The *results* of this operation have been very unfavourable. In the Parisian Hospitals, Nélaton reports of 16 cases during fifteen years, that all have terminated fatally; this mortality, however, including cases that would have died from the injury of the brain for which the operation was performed.

In the Hospitals of Great Britain,—England, Ireland, and Scotland, the mortality although very high, has been much less; and in those of the United States, the proportion, according to Seuter and Gross, is 1 recovery to 4 deaths. The chance of only 1 to 4 in favour of life is sufficient to justify the operation under the pressing circumstances for which alone it is now resorted to,—as the sole chance of preserving life.

**TUMOURS OF THE HEAD.**—(1) The *Scalp* is liable to be the seat of Cysts or Wens, containing sebaceous matter; or Vascular tumours, as Nævi. These Growths do not require any special notice.

(2) The *Cranium* may be the seat of various tumours, the principal forms of which are four in number; ivory exostosis, situated perhaps near the orbit, or on other parts of the cranium; fibrous or fibro-cystic tumour; myeloid tumour; and cancer. Their leading symptoms, diagnosis, and treatment, are conveniently exhibited in the following tabular view, by Mr. T. Holmes.

<i>Tumours of the Skull.</i>	<i>Leading Symptoms.</i>	<i>Diagnosis.</i>	<i>Treatment.</i>
Exostosis.	A small and very hard tumour, growing very slowly, unaccompanied by any symptoms except in very rare cases, when it grows from both tables, or in the orbit and displacing the globe.	From diseased enlargements of the bone; by the presence of symptoms in the latter, and by their less distinct and circumscribed outline.	Operative interference is seldom justifiable.
Fibrous or fibro-cystic.	A slowly-growing tumour, more soft than exostosis, and more liable to affect the brain by growing inwards.	From exostosis, as above; from cancerous tumours by its less rapid growth, and by the other usual diagnostic marks; from fibrous tumour of the dura mater the diagnosis is obvious before perforation of the skull has taken place, but impossible afterwards.	No interference is permissible. Life may be prolonged many years even after the tumour has produced pressure on the brain and cerebral symptoms.
Myeloid.	The same observations apply to the symptoms, diagnosis, and treatment, of these forms of tumour; with the exception that their course is more rapid, and that in all other respects they bear a closer resemblance to cancerous disease.		
Cancer.	Circumscribed pain in head; soon followed by the appearance of a tumour, or by softening and pulsation at the seat of pain. The tumour grows rapidly, and soon produces pressure on the brain. Malignant cachexia is usually well marked. The skull is usually thickened around the tumour.	From innocent tumour, by its more rapid course and by the constitutional symptoms. From hernia cerebri, following absorption of the skull (very rare), by the greater violence of the pulsation, the absence of the movement of the brain dependent on respiration, and the less uniform consistence of the tumour. From vascular tumour (or aneurism by anastomosis), by the cerebral symptoms induced by pressure, and by the signs of cancer.	No treatment is possible.

(3) *The Brain, and its Membranes.*—(a) *Fungous Tumours of the Dura mater.*—Originally described by Louis under this general heading, different kinds of tumour are comprised; some being innocent and some malignant. They all, however, agree in certain particulars, can hardly

be diagnosed from each other, but must be carefully distinguished from other forms of tumour. They are non-congenital, and thus distinguished from nævi and from hernial tumours; and they perforate the skull, which distinguishes them from aneurism by anastomosis and from ordinary solid tumours. At an early period, a general diagnostic sign is the presence of a thin crackling parchment-like layer of bone over the tumour.

The penetration of any tumour through the skull is made known by pulsation communicated from the subjacent brain, and by the cerebral symptoms which pressure on the surface produces; sometimes also, the margin of the opening in the skull can be felt. The tumour is seldom very prominent—often hardly raised above the surface of the skull, but feels like a soft pulsating spot in the bone. Such pulsating tumours may be single or multiple. According to the activity of their pulsation, some diagnosis may be made between these tumours. Active pulsation will probably denote soft cancer; pulsation communicated from the brain may indicate fibrous or fibro-cellular tumour. Some of these perforating tumours are not entirely of intra-cranial origin, but spring also from the diploe of the bone; and thus the diagnostic character of pulsation becomes very equivocal.

The *course and termination* of these tumours depend entirely on their nature. The innocent tumours are assuredly not necessarily fatal; a fibrous tumour of the skull and dura mater has been known to produce occasional symptoms of compression for more than fifteen years, and yet the patient died at a tolerably advanced age, and of another disease unconnected with that on the skull.

No *treatment* of any operative kind for the removal of these tumours, will be warrantable or effectual.

(b) *Congenital Hernial Tumours of the Brain, and Membranes.*—Encephalocele and Meningocele are hernial tumours, respectively, of the brain and its membranes, or of the membranes alone, the protruding bag being filled with sub-arachnoid fluid; and both kinds of tumour result from congenital deficiency of the bone in some part of the skull, usually the occiput. The tumour thus formed varies in size from a pea to a protrusion exceeding the child's head; it is soft, rounded, and bluish in colour where covered by thin skin. Such a tumour resembles nævus; in its congenital formation, colour, and increasing size when the child cries; and it is also difficult to distinguish from congenital encysted tumour. The subject of this malformation is usually still-born or dies early; occasionally the child lives to an adult age.

*Treatment* by any operative interference will scarcely be justifiable. But,—as with spina bifida—when the protrusion is rapidly increasing and threatening to burst, a puncture, followed by evenly adjusted support, may be resorted to. In one case, an encephalocele was sliced off, and the patient survived.

*HYDROCEPHALUS, and PARACENTESIS CAPITIS.*—Sometimes the Surgeon is called upon to puncture the head, to relieve symptoms of compression in an otherwise fatal case of hydrocephalus, in childhood. This operative procedure consists in introducing a very fine trocar and canula, perpendicularly through the anterior fontanelle, away from the longitudinal sinus. Two or three ounces of the serous fluid having been allowed to escape, the puncture is closed with a piece of lint, and the temporary support of a bandage to the head may be advisable. The operation may have to be repeated occasionally, at perhaps intervals of two or three weeks.

## ORGANS OF SPECIAL SENSE, AND THEIR APPENDAGES.

## CHAPTER XL.

## OPHTHALMIC SURGERY; OR INJURIES AND DISEASES OF THE EYE, AND ITS APPENDAGES.

A CONDENSED view of the Injuries and Diseases of the Eye, will meet the requirements of the Student and the Practitioner, in the special department of Ophthalmic Surgery, as part of a general work on Surgery.

## INJURIES.

WOUNDS.—(1) The *Eyebrows* and *Eyelids* are liable to the Injuries of other soft parts.

*Incised* wounds or cuts are of common occurrence, whether by accident or violence. The mobility of these parts, subject to the twitching action of the corrugator supercilii and levator palpebræ muscles, disturbs the process of adhesion and renders cicatrization irregular, with proportionate disfigurement and probable eversion or inversion of the lid.

The consequences of any such wound may be serious, although the Eye itself escape direct injury; loss of vision ensuing from concussion of the retina or effusion of blood in the eye.

The *treatment* of the wound is simple. The lips of integument must be evenly adjusted, and retained by two or three points of fine suture, as the extent of incision may require. Water-dressing and rest will then probably prevent inflammation, and promote union.

(2) The *Eye* itself is also liable to the lesions of other soft parts; but, being lodged within the cavity of the orbit, it more frequently escapes injury.

*Wounds* are, however, met with occasionally. An *incised* wound or clean linear cut, may be caused by a piece of glass, or the edge of some cutting instrument. Both these occasions of incision I have seen. In the latter case, the end of a sharp chisel suddenly broke off and flew into the eye of a man who was using the instrument, dividing the cornea and lodging deeply in the globe of the eye. It was withdrawn by Mr. Murphy, Senior House Surgeon at the Hospital. The fragment measured,  $\frac{3}{4}$ ths of an inch in length,  $\frac{1}{8}$ ths in breadth; and it weighed 39 grains. Subsequently I extirpated the eyeball on account of cerebral symptoms, and threatened sympathetic affection of the other eye. The patient made an excellent recovery, and that eye remained unaffected.

Prolapsus of the iris may arise from an incised wound of the cornea; the aqueous humour escaping, and the iris protruding through the wound.

*Penetrating* wounds of the eye are of a lacerative character, being produced, in most cases, by some blunt-pointed instrument; which not unfrequently passing beyond the eye or to one side of it, may penetrate the orbit also, and the brain; fracture and wound of the brain thus most seriously complicating the injury, or proving fatal. Such wounds have been occasioned by a fork or steel pen, by a thrust with the point of an umbrella, or a spine of wood abutting from a tree and meeting the eye of a person who was running through a wood. An explosion of gunpowder may throw grains of powder into the eye, or grit by the force of explo-

sion; or a stray shot from a gun may enter the eye. Both the eyes of Mr. Fawcett, M.P., were accidentally destroyed by a shot which centrally penetrated the cornea of either eye. In the diabolical outrage at Clerkenwell by the firing of a barrel of petroleum and gunpowder, both eyes of a little boy—one of the victims under my care at the Royal Free Hospital—were destroyed, and his mother lost her left eye entirely in like manner.

The *consequences* of any *penetrating* wound are always formidable. The eyeball is disorganized, either by the wound or by consequent sup-puration, followed by prolapsus of the iris; or the eye itself escaping injury, amaurosis ensues either from lesion of the optic nerve or as the result of sympathetic irritation of other orbital nerves. A penetrating fracture of the orbit, and wound of the brain, have obviously most serious consequences. In one case recorded by Nélaton, a singular result followed. The cavernous sinus and internal carotid artery on the opposite side were wounded by the thrust of an umbrella into the orbit; an arterio-venous aneurism formed protruding the eyeball, and fatal hæmorrhage ensued. Lastly, loss of vision in the other eye may result from sympathetic irritation, transmitted apparently through the optic commissure.

*Treatment.*—Nothing, of course, can be done to a wound of the eyeball to facilitate repair of the lesion itself; but the consequences of inflammation with regard to this organ and the brain, must be promptly anticipated. Perfect rest in a darkened room, with local blood-letting, blistering, and the administration of calomel and opium, constitute the principal preventive measures. Antimony or anything likely to produce sickness must be avoided, and also active purgation; the efforts of straining in vomiting or defecation affect the eye unfavourably, and peril prolapsus of the iris.

This additional lesion having occurred; the iris may be reduced by very gently rubbing the lid against the cornea, over the prolapsed portion, aided by a drop or two of solution of atropine let fall into the eye. This will also be the best precaution against the occurrence or the recurrence of prolapsus, by ensuring dilatation of the pupil. Strangulation of an unreduced prolapsus soon supervenes, rendering reduction impossible. If prolapsus of the iris cannot be reduced, whether in the first instance, or owing to strangulation; the protruding portion may be snipped off with fine curved scissors to prevent any irritation of the eye by its presence, but the removal of this portion of the iris endangers further protrusion. Hence, a large prolapsus may require excision; otherwise it had better be allowed to remain, and the projection will probably disappear spontaneously. The iris plugs up the aperture at the level of the cornea, and cicatrization rapidly ensues, leaving a somewhat opaque scar. Any application of nitrate of silver is unnecessary or injurious.

Adhesions of the iris may, perhaps, be prevented by the anti-inflammatory measures above indicated, especially by calomel and opium.

Opacity of the lens or its capsule, forming traumatic cataract, may eventually necessitate an operation for its extraction.

Disorganization of the eyeball, by or in consequence of a penetrating wound, will probably necessitate extirpation of the organ; as in the case already noticed.

*CONTUSION.*—Blows on the eye produce contusion; restricted to the eyebrows and lids, with the ordinary appearance of "black-eye," or involving the eyeball, with peculiar appearances.

*Black-eye* consists of an extravasation of blood into the subcutaneous cellular tissue of the eyelids; presenting the usual discoloration of ecchymosis, and undergoing various shades of colour from black to green and yellow, as it disappears. The subconjunctival texture is likewise infiltrated. Concussion of the retina sometimes accompanies this palpebral lesion, followed by loss of sight, temporarily or permanently.

Contusion of the *eyeball* presents the appearances of blood extravasated into the chambers of the eye, and especially into the anterior chamber, partly or wholly concealing the iris and pupil. Extravasation may here also undergo absorption, in a period varying from a week or two to some months, according to the suppression of inflammation.

*Rupture* of the eyeball, produced by a blow, is always a very serious injury; comprising escape of the aqueous humour, with perhaps detachment of the iris, or dislocation of the crystalline lens forwards into the anterior chamber or backward into the vitreous humour. Sometimes, this humour escapes, and the globe of the eye collapses. Intense inflammation follows any rupturing injury.

The *treatment* of contusion varies with the damage done. An ordinary black-eye may be left to itself, or the disfigurement chased away by arnica lotion. The mouse's-back bruise produced by the pounding fist of a prize-fighter, has, I believe, been removed by puncturing and sucking out the blood. Contusion involving the eyeball must be promptly met by measures preventive of inflammation; while rupture of the ball usually requires some kind of operative interference. Thus, an artificial pupil may have to be made, or displacement of the lens rectified. Collapsing rupture will probably require, or lead to the necessity of extirpation of the remnant organ.

**FOREIGN BODIES.**—Various kinds of foreign bodies are apt to enter the eye; a grain of sand or particle of brick or mortar, lime, flint, shot; or other matter to which the eye may perchance be exposed by occupation, amusement, accident, or in the event of malicious intent. Such bodies lodge commonly in the conjunctiva, and under either lid; occasionally they are impacted in the cornea, or penetrate deeply into the eye.

The exposed part of the eye can readily be inspected; the inside of the lower lid and lower part of the globe, simply by depressing the lid with the finger, so as to evert the lid, while the patient is desired to look up; or the upper lid and corresponding part of the globe can be examined by raising the lid as the person looks downwards. To completely inspect this lid, it is necessary to evert it; a little procedure easily accomplished by laying a probe across the globe of the eye at the back of the lid, then taking the eyelashes between the finger and thumb and turning the lid upwards over the probe, thus exposing the palpebral cartilage. Sometimes, however, the eye is shut forcibly and screwed up, by the pain of irritation, or timidity of the patient; and eversion cannot be at once effected.

*Treatment.*—Removal of a foreign body from the conjunctiva, may generally be accomplished by a light touch with a probe or fine scoop, the hand resting steadily on the cheek; or a camel's-hair brush may be employed more effectually, and the eye swept round to remove more than one particle. In the Welsh iron-mining districts, the workmen have a knack of skilfully licking out a particle of iron from the eye; a nasty mode of performing a nice ophthalmic operation, but it answers well, and the tongue-brush is always ready for any emergency. Powder, of any

kind, must be syringed out with water ; and lime may at the same time be neutralized by thus applying weak vinegar-and-water.

Abrasion of the conjunctiva sometimes occurs, without the presence of a foreign body, as by the scratch of a finger-nail ; and any such injury will occasion more pain, if less irritation, than a rough particle in the eye. A drop of castor oil, is, according to Mr. Bowman's experience, the most soothing application.

It should be remembered, that after the removal of a foreign body from the eye, the sensation of its presence remains for some time, with continued redness of the conjunctiva and lachrymation. This sensation is sympathetic, and practically misleading.

Impacted and penetrating foreign bodies must be extracted as soon as possible.

Inflammation subsides, in many cases, after removal of the cause, but it must be subdued should it continue.

#### DISEASES.

DISEASES OF THE EYELIDS.—(1) *Hordeolum*, or *Stye*.—A minute boil, beginning at the edge of the lid, as a small, red, hard swelling, accompanied with itching and a sense of stiffness. The whole lid may become involved, and the eye closed. Matter forms and discharges from the summit of the boil, a small slough of cellular texture escapes, and the red swelling subsides and disappears. Sometimes, this furuncular inflammation remains indolent, without suppuration.

Weak and scrofulous children are most subject to this affection ; adults far less commonly.

*Treatment* consists in warm fomentations or poultices, until pointing occurs ; with tonics, attention to the bowels and diet. Indolent stye may advantageously be touched with nitrate of silver.

(2) *Abscess in the Meibomian follicles*.—An obstructed follicle, containing retained secretion, forms a minute, solid, granule, which irritates the eye. Abscess of the follicle follows. The lower lid is commonly affected.

The *treatment* is simply a puncture and evulsion of the small nodule of stearine by means of a scoop ; then the irritation subsides.

(3) *Ophthalmia tarsi*.—Inflammation at the roots of the eyelashes, forming minute pustules, which, discharging, encrusts and mats the eyelashes together, and gums the eyelids during sleep. The hairs become misplaced and inverted, constituting the state named *trichiasis* ; or the hair-bulbs are destroyed, and the hairs shed, leaving the margins of the lids ulcerated and raw, or rounded into a smooth, red, shining cicatrix, having neither hairs nor meibomian orifices. Superadded to this state, the puncta may be obliterated, the tears running over the cheeks, causing irritability and blinking of the lids, and thus constituting the condition properly named *lippitudo*.

*Treatment*.—Any accumulation of crusts must be carefully washed off night and morning, in order to remove this source of irritation, and to make applications to the minute sores at the roots of the hairs. For this twofold purpose, also, they may be kept closely cut with scissors. Stimulating ointments should then be applied, such as the diluted ung. hydrarg. nitratis, by a small camel's-hair brush. Lotions are useful adjuncts—*e.g.*, the acetate of lead, from two to four grains in the ounce of distilled water. With *ulceration*, the hairs should be plucked out. *Lippitudo* may be

much relieved by slitting up the canaliculi. The general treatment throughout must be tonic, and have special regard to the state of the digestive organs.

(4) *Trichiasis* is an irregular growth of the eyelashes, the general form of the eyelid remaining unaltered, and the ciliary misplacement arising from any cause. A single hair, or several, may be affected, with proportionate irritation and a constantly watery state of the eye.

The *treatment* is simple, and often effectual. The offending hair or hairs must be removed; a single hair, by forceps with a slow, steady pull so as not to snap it and leave the root; or several hairs may be removed by dissecting out the small portion of lid, external to the tarsal cartilage, in which their roots are implanted, and uniting the wound with a suture.

(5) *Entropion*.—An *inversion* of the lids, as distinguished from *trichiasis*, which is a displacement, chiefly by in-growth, of the eyelashes. But the two conditions are frequently associated. Both occasion the same symptoms of irritation of the eye, and are aggravated by their concurrence. Entropion arises from various causes, and thus presents certain special and incidental symptoms. Spasm of the orbicularis palpebrarum muscle in the irritable ophthalmia of children, is the simplest form of entropion, and as affecting the lower lid; a similar spasmodic inversion happens in the relaxed lower lid of old persons. Chronic inflammation of the palpebral conjunctiva occasions a far more severe and obstinate entropion, the upper tarsal cartilage curving upon itself, until the whole range of eyelashes turns backwards against the globe. Contraction of the conjunctiva, consequent on prolonged stimulation by nitrate of silver or sulphate of copper, or cicatrization following injury from acids, caustic alkalies, or burns; are occasional causes.

*Treatment* must of course have reference to any cause in operation. Various procedures have been devised to counteract the resulting inversion. *Excision* of an elliptical portion of the skin of the lid, together with the subjacent fasciculus of muscle, and then uniting with fine sutures; may effect a cure in a flaccid lid, subject to spasmodic inversion. Care should be taken lest, by removing too large a portion of skin, an opposite state, eversion of the lid, be produced. An *extreme* degree of inversion, by incurvation of the tarsal cartilage, may be overcome by Mr. Streetfeild's expedient. The skin of the lid having been dissected up, a long, narrow, wedge-shaped slice is excised from the tarsal cartilage, forming a groove extending the whole length of the tarsus. Excursion is thus produced, and the flap of skin being replaced is united with sutures.

Trichiasis may require removal of the eyelashes, with the portion of tarsal margin containing their roots.

(6) *Ectropion*—*eversion* of the lids, is the opposite condition to entropion. The appearance of the inner surface of the lids—the conjunctiva, red, swollen, and discharging, will be readily recognised. Eversion arises either from chronic thickening of the palpebral conjunctiva, which presents granular excrescences—the state known as *granular lids*; or, from contraction of the skin, by cicatrization, as after a burn on the cheek.

*Treatment*, here also, must have reference to the cause in operation, and to the resulting deformity. Thickening of the conjunctiva may be reduced by the moderate application of nitrate of silver, or diluted ung. hydrarg. nitratis, diluted ung. hydr. nitrico-oxydi, or diluted ung. zinci oxydi. This failing, a portion of the palpebral conjunctiva must be excised, that the lid may be restored to position by contraction; and it

may be necessary to remove also a wedge-shaped piece of the tarsal cartilage. An everting cicatrix of the eyelid is best remedied by the transplantation or transposition of a portion of adjoining healthy skin.

(7) *Epicanthus*.—A crescentic fold of redundant skin at the inner corner of each eye, partly or wholly concealing the caruncle. Associated with a depression of the nasal bones, the face has a laterally stretched, Chinese expression. This disappears somewhat, as, in after life, the bridge of the nose rises, and carries up the fold of integument.

The only cure is by pinching up a vertical fold of skin between the eyebrows, removing it, and uniting with sutures.

(8) *Union of the Lids*—*Ancyloblepharon*.—This state may be partial, and resulting from ulceration, or complete and congenital.

Division of the junction, and separation of the lids, will sometimes prove successful.

(9) *Union of the Lids to the Globe*—*Synblepharon*.—This state also may be more or less complete, but it is, I believe, always of traumatic origin; the adhesions resulting from destruction of the opposed surfaces of conjunctiva, as by quick-lime injury or a burn. One of the worst cases I ever saw, was owing to an accidental thrust in the eye with a hot poker.

Division of the adhesions and separation of the surfaces, is the only mode of cure. But union is apt to return, to obviate which, Mr. Walton divides the band vertically, through its entire thickness, and brings the edges of each side severally together by sutures.

(10) *Hare Eye*—*Lagophthalmos*—is an open state of the eye, arising from various causes. Structural conditions, as the contraction of a cicatrix, resemble ectropion; and are amenable to the same treatment. Paralysis of the orbicularis muscle, from various conditions affecting the facial trunk of the seventh nerve or portio dura, allows the levator palpebræ to act unopposed, and thus keeps the eye open. Exposure to cold may have this paralyzing effect temporarily; or it may depend on some more centric and permanent cause, as a tumour in the course of the nerve, disease of the petrous portion of the temporal bone transmitting the nerve, or upon congestion of the brain.

The treatment will be guided entirely by the apparent cause. Temporary paralysis may be relieved by derivation—a blister behind the ear.

(11) *Ptoſis* is a drooping of the upper lid, owing to paralysis of the third, or motor-oculi, nerve; the eye itself is abducted, the pupil dilated and fixed, and vision somewhat impaired. The eyelid is smooth and unwrinkled, and the forehead furrowed by the frequent action of the occipito-frontalis muscle, in attempting thus to raise the lid. Head-ache, giddiness, and other cerebral symptoms, may denote congestion of the brain as the cause; or ptoſis may be symptomatic of general debility.

*Congenital* ptoſis sometimes occurs, and then, probably, the levator palpebræ muscle is altogether wanting.

The treatment of ordinary ptoſis must be directed to the removal of cerebral congestion, by derivation and purgatives, followed by stimulants and tonics; or, when depending on general debility, the latter kind of remedial measures will be alone appropriate. Ptoſis, otherwise incurable, may perhaps be remedied by an operative procedure—removal of a portion of skin from near the eyebrow, in order that the lid may be subject to the elevating action of the occipito-frontalis muscle. This should not

he had recourse to when double vision would be established by the abducted state of the eye.

(12) *Spasmodic twitching* of the orbicularis muscle is accompanied with a visible quivering of the skin of the eyelid, known as *live-blood*. Either lid may be affected, commonly the lower one. It appears to be symptomatic of intestinal irritation, especially by ascarides.

*Treatment* will chiefly consist in the administration of purgatives and tonics.

(13) *Hysterical Affection of the Eyelids* is characterized by sudden and acute paroxysms of pain in the lids and eyes, aggravated by slight pressure, and occurring in girls or young women otherwise subject to hysteria. I have not met with any notice of this affection in books, but I have seen a well-marked case in a young lady, who also suddenly—in two days—lost the sight of her right eye, and so completely that she could only discern the glimmering of a strong light with that eye. The organ itself was not diseased in any way; although carefully examined with the ophthalmoscope, no change could be detected. Menstruation was healthy.

Chloroform seemed to me likely to prove the readiest means of subduing the paroxysms in this case; and having administered it on one such occasion which I happened to witness, the pain ceased, but returned as the anæsthetic influence passed off; on renewing it, the pain again subsided, and the patient slept the remainder of the night. Next morning, she was as well as ever; the amaurosis remaining.

(14) *Morbid Growths or Tumours of the Lids*.—The same tumours as in other parts of the body, are liable to occur in the eyelids, only on a smaller scale. Thus may be enumerated, more particularly; cysts, enlarged sebaceous follicles, warts, nævi, and cancer including the epithelial variety. The pathology of these growths, as affecting the lids, scarcely requires any special notice, and particulars of this kind will be found in works on Ophthalmic Surgery.

The *treatment* is not peculiar; growths situated in the eyelids must be removed, either by careful dissection, or by fine ligature.

*Lice*,—phthirius or crab-lice, as distinct from pediculi of the scalp—sometimes lodge about the roots of the eyelashes. They occasion an intolerable itching, and the lashes present a powdery appearance, clogging the roots with yellowish-grey and brown crusts, so as to resemble ophthalmia tarsi. But the movements of the insects may be detected.

White precipitate ointment, — ung. hydrarg. ammonio-chloridi—smeared into the roots of the eyelashes, will soon destroy the enemy.

DISEASES OF THE LACHRYMAL APPARATUS.—This appendage to the Eye consists; of the lachrymal gland, situated within the outer angle of the orbit, which secretes the tears to moisten the eye; the puncta and canaliculi, situated at the inner angle of the eye, which drain away any superfluous fluid into the adjoining lachrymal sac, as a temporary receptacle, and of the lachrymo nasal canal or duct, which conveys such fluid into the lower meatus of the nose.

(1) *The Lachrymal gland*.—This small almond-shaped body is rarely the seat of injury or disease. Sheltered, in a recess, within the outer angular process of the frontal bone, the lachrymal gland is not exposed to violence; and it seldom participates in the inflammation of neighbouring tissues, nor seems subject to disease commencing in its structure.

Inflammation, acute and chronic, and growths, simple and malignant, are described by some writers, especially foreign authors.

The *ducts* of the lachrymal gland are liable to become obstructed, forming a small cyst-like tumour in the upper eyelid—*dacryops*, which is plainly seen when the lid is everted. Puncture of the cyst is apt to be followed by a minute fistulous aperture in the skin, through which the secretion continually distils. This *dacryops fistulosus* may be remedied, by passing a thread through the opening and thickness of the lid, bringing it out at the conjunctival surface. A knot having been made at one end, this end is drawn into the fistula, and by continued traction of the other end, the knot is made to ulcerate its way through the conjunctival surface. The tears thus being diverted, the fistulous aperture may be closed by paring and uniting its edges.

*Tumour* of the gland presents a lobulated enlargement at the outer angle of the orbit. Extirpation is the only remedy. This operation may also have to be performed to overcome the inconvenience of an overflow of tears, when the puncta and canaliculi, at the inner angle of the eye, have been wholly destroyed by an extensive burn. In three such cases, Mr. Dixon has extirpated the gland; and these are the only instances of this operation which have fallen within his experience. The gland has been removed with the eye; and sometimes it has been involved in the disease of this organ, but more frequently found in a healthy state.

(2) *Lachrymal Obstructions*.—The puncta, canaliculi, the lachrymal sac, and the nasal duct, are severally liable to become the seat of obstruction; and far more frequently than the excretory ducts of the gland itself. Thickening of the delicate lining mucous membrane, would seem to be the cause of obstruction, in each of these portions of the lachrymal excretory apparatus.

*Epiphora* is an overflow of tears, and may therefore be symptomatic of any lachrymal obstruction on the nasal side. Obstruction of the *puncta* or of the *canaliculi* will be attended with a complete overflow; none of the secretion finding its way into the sac. Obstruction of the *nasal duct*, by stricture, necessitates an accumulation of the tears and mucus, within the sac; forming a swelling—*mucocoele*, just below the inner angle of the eye. The distended sac becomes inflamed and suppurates, forming an abscess; and this at length discharges itself through an opening in the skin, constituting *fistula lachrymalis*.

The appearances of these transitional states are too obvious to need description. The fistulous opening is generally beset with fungus granulations, owing to the constant irritation of the trickling discharge. Further destruction of the surrounding skin, or even of the bony casement of the sac, sometimes occurs. Or, the fistulous opening contracts to a small pin-hole aperture, resembling one of the puncta.

*Treatment*.—The cause of obstruction must be removed, and for this purpose, its seat must be reached. Inflammatory thickening of the membrane lining the sac and nasal canal, may be lessened by small oval blisters applied over the sac. Astringent lotions of alum or tannin dropped into the eye, pass through the puncta to the thickened membrane. Acute inflammation should be met by warm fomentations and water dressing; and when abscess has supervened, an incision must be made into the sac and the pus evacuated. The general health should be attended to, according to its condition in the course of the case. Tonics will generally be indicated.

*Operative removal of the obstruction.*—The proceeding which will be appropriate, varies with the seat of obstruction.

The *puncta* may be contracted; and then, Mr. Bowman recommends that one of them should be cut across close to the obstruction, and the *canaliculus* slit up on a fine probe. When the *canaliculus* is the seat of contraction, the sac may be punctured below the *tendo-oculi*, and the canal slit up on a fine probe run into it from the sac up to the point of obstruction. The *tendo-oculi* is easily found as it crosses the sac, by pressing with the point of the finger on the inner side, and thus putting the tendon on the stretch. *Displacement* of the *puncta*, resulting from thickening of the conjunctiva by chronic inflammation, is to be remedied in another way. Mr. Bowman slits up the canal from the punctum to a spot where it can catch the tears before they overflow the margin of the lid. After either of these operations, the probe must be introduced for several days to prevent closure of the wound.

The *lachrymal sac* and *nasal duct* are, perhaps, more commonly the seat of obstruction, by thickening of the lining membrane forming stricture. The last mentioned operation—that of slitting up a *canaliculus* from the punctum, affords a ready entrance to this portion of the lachrymal excretory apparatus. The tarsus being put on the stretch, a probe of sufficient thickness is introduced—best by the Surgeon standing *behind* the patient—and passed along the opened *canaliculus*, until its extremity strikes against the inner wall of the sac. Then, keeping it there, the probe is raised to a vertical position, and carefully slid downwards to the seat of stricture; observing to take the direction of the canal, somewhat backwards and outwards. The instrument is thus passed into the nasal cavity, and on withdrawing it, the contents of the sac may be pressed down into the nose, or after any temporary swelling has been reduced by fomentation. This proceeding must be repeated from time to time, until a cure is effected; just as in the treatment of stricture of the urethra by gradual dilatation. There is this, however, important difference; that, as the lachrymo-nasal duct is ensheathed in a bony canal, thickening of its lining mucous membrane takes place concentrically; any undue violence therefore, would only increase the inflammatory thickening, instead of lessening the stricture.

The introduction of a *style* (Fig. 323) through the sac and allowing it to remain in the nasal canal, is another mode of treatment. The transverse tendinous cord being put on the stretch, a narrow, straight, sharp-

FIG. 323. pointed bistoury, is entered perpendicularly, below the cord, into the sac (Fig. 324); and then the style may be conveniently slid along the blade through the sac, into the nasal duct, leaving the black-button head of the style over the puncture. The object of this procedure is to maintain the passage, and enable the tears to glide down between the solid

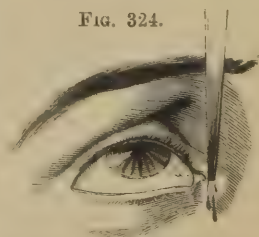

style and the lining membrane, into the nose. But the consequent irritation and return of stricture when the use of this instrument was discontinued, has led to its disuse comparatively. This mode of treatment was analogous to the cure of strictured urethra by suppur-  

FIG. 324.

*Dacryoliths*.—Concretions, by deposition of the earthy salts of the tears, sometimes form in the canaliculi or in the sac. This occasion of obstruction, is also attended with the constant overflow of tears, swelling in the situation of obstruction, inflammation, and perhaps suppuration.

The introduction of a probe into the canaliculus, or thence into the sac, will detect the presence of the concretion; which must then be removed by an incision, a scoop being used to extract the foreign body.

A *detached eyelash* sometimes intrudes into one of the canaliculi; its point protruding irritates the caruncle and semilunar fold; or it may almost escape detection.

Removal of the hair with a fine forceps, will at once terminate this inconvenience.

**DISEASES OF THE CONJUNCTIVA.**—(1) **CONJUNCTIVITIS, OR OPHTHALMIA.**—Inflammation of the conjunctiva, originating in this membrane, presents certain characteristic appearances; and whereby it can be distinguished from inflammation of the sclerotic coat of the eye itself, or scleritis—a very important diagnosis.

*Symptoms.*—Conjunctivitis is denoted by bright scarlet redness of the conjunctiva; most apparent on the inner surface of the lids and junction around the sclerotic coat of the eye, but shading off as it approaches the cornea; and this redness consists of a network of the conjunctival vessels, which are plainly seen owing to their open arrangement and large size. On the other hand, the redness of scleritis is most marked around the edge of the cornea, in the form of a dusky pink zone—sclerotic zone, shading off as it disappears backwards beneath the fibrous expansion of the recti muscles; and this zonular redness is simply a uniform tint without visible anastomosis, the sclerotic vessels being closely set together and of smaller size. Sclerotic redness is characteristic of several forms of disease in the deep-seated tissues of the eye; and therefore the twofold distinctive features of its situation and the vascularity, as compared with conjunctivitis, should be carefully noted by the student and observed in practice. The additional symptoms of conjunctivitis are, smarting, heat, weight, and stiffness in the lids, and as the disease advances, a sensation as if a grain of sand were rubbing between them and the globe. There is a more or less abundant flow of tears or lachrymation, particularly on exposure of the eye, and some intolerance of light.

The *causes* of this simple and typical form of the disease may be;—slight local irritation, as by an inverted eyelash or other small foreign body in the eye, or exposure to cold and damp; disorder of the digestive organs and general debility. March winds and dyspepsia co-operating, frequently give rise to ordinary conjunctivitis.

*Treatment.*—The removal of any source of local irritation must, of course, be primarily attended to. Remedial measures should then have reference to the state of the inflammation, and of the general health. Topical bleeding, by a leech or two or cupping to the temple, will rarely be necessary; derivation by blistering, and weak astringent lotions or eye-washes, are generally appropriate. The liquor plumbi diacetatis, fifteen minims to the ounce of distilled water, forms a useful collyrium. Spermaceti ointment may be smeared on the eyelashes at bed-time, when there is any tendency to gumming of the lids during sleep. The general treatment should not be of a lowering character; active purgation will rarely be requisite, but regulation of the bowels and the correction of any error of diet, constitute the plan of treatment. Thus, a stomach mixture,

consisting of bicarbonate of potash, the diluted hydrocyanic acid, with the tinctures of gentian and rhubarb, may often be prescribed with great benefit; combined with plain nutritious food. Tonics will often have to be resorted to; quinine and iron or the mineral acids

*Varieties of conjunctivitis are worthy of differential notice.*

(a) *Catarrhal Ophthalmia*.—A peculiar characteristic of this variety—observes Mr. Dixon—is the existence of numerous red blotches at different parts of the network of vessels, produced by some of these having given way and allowed their blood to become extravasated. The extravasations vary much in size; some being as small as a pin's head, others almost equal the breadth of the cornea. Mucous secretion, little at first, may subsequently become so profuse as to resemble another variety of Ophthalmia,—the *purulent*. Sometimes, the sclerotic is involved, as denoted by a pink zone at the margin of the cornea; and, the subconjunctival cellular tissue becoming infiltrated, the conjunctival membrane is raised over the sclerotic into a bleb containing serous fluid, an appearance which ceases abruptly at the margin of the cornea. This elevated condition of the inflamed conjunctiva, is named *Chemosis*. The upper eyelid also frequently becomes œdematous, and overhangs the lower lid,—in this mixed state of conjunctival and sclerotic inflammation.

*Treatment*.—The unmixed state of inflammation,—when the conjunctiva alone is affected, and without constitutional disturbance, requires no further treatment than the local application of nitrate of silver in solution,—two grains to the ounce of distilled water, which should be dropped into the eye, twice or thrice a day. Previously to using the drops, the conjunctiva should be cleansed with warm water. This being continued for a week, it may then be used once a day, for perhaps a week longer, when the cure will be complete. If the sclerotic and perhaps the cornea have become implicated; nitrate of silver must be omitted, and the inflammation treated as when these textures of the eye are alone affected.

(b) *Pustular Ophthalmia* is characterized by little, reddish, aphthous-like elevations on the conjunctiva, having whitish centres, but not containing pus; and each surrounded by a plexus of blood-vessels. The cornea is never involved. This variety of ophthalmia frequently occurs, particularly in children.

The *Treatment* is not peculiar; a blister to the temple, and weak astringent lotions of diacetate of lead, generally prove sufficient; the constitutional health being attended to.

(c) *Purulent Ophthalmia*.—In this variety of the disease, the *cornea* is very liable to become involved; thus constituting its distinctive peculiarity. Three sub-varieties are recognised; purulent ophthalmia, as it occurs in *adults*, in *new-born infants*, and that of *gonorrhœal* origin. But, they all agree in implicating the cornea, and also often resemble each other so closely, as not to be distinguished otherwise than by their respective origins.

Purulent ophthalmia, in a well marked state, presents the following appearances. The lids are dull red or purple, swollen and œdematous; when drawn apart, thick yellow purulent secretion oozes out from the conjunctiva, and if allowed to dry, forms a crust, concealing the eyelashes. The patient cannot open his heavy eyelids, and is pale and depressed, the more so with the belief that he is blind. Chemosis exists to such a degree as to overlap the cornea, and ulceration or sloughing of the cornea supervenes. The former commences at the extreme margin of

the cornea, underneath the overlapping chemosis, and might therefore escape observation; extending as a deep crescentic groove, perforation ensues, and prolapsus of the iris, which appears as a small dark nodule at the bottom of the ulcer, with some collateral deformity of the pupil. Sometimes, the ulcerative groove extending around the cornea, isolates its central portion which bulges as a whitish or opaque shield; or becoming thinned it is darkened by mixed fibres of the protruding iris. Sloughing of the cornea is preceded by yellowish opacity and dulness of the surface, the cornea having the appearance of wash-leather; softening and shreddy disintegration of the cornea ensues, the whole iris bulges with it, and with fibrous exudation, constitutes a *staphyloma*.

Purulent ophthalmia is communicable by contact with the purulent secretion,—it is a contagious disease. It is most common in hot climates, hence named Egyptian Ophthalmia; and I often saw the disease at Constantinople, during the Crimean War. It also occurs most frequently in this country during the hottest months,—July and August, particularly during the prevalence of an east wind. Dust irritating the conjunctiva is a predisposing cause.

*Treatment*.—Arrest of the purulent inflammation, in time to prevent ulceration or sloughing of the cornea, is the grand indication. Local measures consist in the frequent use of astringent lotions; nitrate of silver, three or four grains to the ounce of water; or alum, in the proportion of eight or ten grains to the ounce. These eye-washes may be applied by sponging or syringing, three or four times a day. Ulceration itself can sometimes be arrested by touching the spot with a fine pencil of nitrate of silver or probe coated with the fused salt.

Chemosis, having formed, threatens destruction of the cornea, apparently by strangulation of the surrounding sclerotic vessels. Tension must, therefore, be at once relieved. This is accomplished by incising the swollen conjunctiva, from the cornea to its palpebral reflection, on either side of the eye; care being taken in using a small curved bistoury, not to wound the sclerotic coat. Warm fomentations will aid the bleeding and discharge. The general treatment equally has in view the liability to ulcerative destruction of the eye, especially in a weak debilitated subject, whose power of assimilation has already failed. Tonics and a nutritious diet, are, therefore, far more appropriate than any depletory measures. Opiates may be combined with advantage to allay the irritability of weakness.

*Purulent Ophthalmia, in new-born infants*.—*Ophthalmia neonatorum*, commences within a few days of birth, usually about the third day. The symptoms much resemble those of the disease in adults. The tumid overhanging upper lids is a conspicuous feature; and on the slightest pressure, a pea-like drop of thick, yellow pus starts out from the inner canthus. Ulceration and sloughing of the cornea are equally imminent.

The *cause* of this disease in new-born infants is the contact of some morbid discharge from the mother, at the time of birth. Possibly, this discharge may be of a gonorrhœal character; but leucorrhœa would seem to be another source of contagion.

*Treatment* is precisely similar to that of the disease in adults. All antiphlogistic measures must be carefully avoided; a moderate strength of astringent eye-washes, diligently used, with tonics, as a few drops of Battley's liquor cinchonæ, and a free suckling of the child, constitute the plan of treatment whereby destruction of the eye may be prevented.

(d) *Gonorrhœal Ophthalmia* is essentially the same in its symptoms as those of ordinary purulent ophthalmia; but it differs in being far more severe and destructive, and in its origin. It is caused by the application of gonorrhœal matter from the urethra to the eye. Both eyes are often affected, and usually at an interval of a few days; the eye attacked last generally suffering least. The presence of gonorrhœal discharge from the penis will throw light on the diagnosis; and a patient having violent conjunctivitis but who denies having contracted any urethral discharge, should always be examined.

The *treatment* is substantially that of ordinary purulent ophthalmia, as already directed. But the measures indicated must be even more promptly applied,—more preventive. With every precaution, ulceration frequently happens; still the treatment should be pursued in the hope of retaining a small portion of the cornea, transparent, for the purpose of making an artificial pupil eventually and thus preserving even partial vision. This will be a greater boon if both eyes are affected; lest the filming opacity darken into total blindness.

(e) *Scrofulous Ophthalmia*.—This is essentially a disease of the *cornea*, the conjunctiva being only secondarily affected. One or more small whitish elevations,—*phlyctænula*, or perhaps pin-head ulcers, beset the cornea, which is otherwise hazy, with a long plexus of vessels running from the corneal margin to the morbid spot. This lash of vessels is quite diagnostic of the disease; there is some zonular redness in the sclerotic, immediately around the cornea, but no general vascularity of the conjunctiva. Great intolerance of light—*photophobia*, is another characteristic, with violent spasmodic contraction of the orbicular muscle,—closing the eyes forcibly, when any attempt is made to examine them. This symptom is often out of all proportion to the extent of corneal disease; co-existing probably with only one *phlyctænula* or ulcer and its lash of vessels, on almost a clean cornea. Lachrymation is profuse, the tears gushing out whenever the lids are the least separated; and there is often some excoriation of their margins. The patient thus habitually avoiding the light, acquires a sort of frowning and downcast look, and prominent brow, resulting from constant action of the corrugator muscles. Add to these appearances, the concomitant marks of scrofula in other parts of the body, and the picture of scrofulous ophthalmia is complete. It chiefly affects children, but may be seen in adults.

*Treatment*.—The general health is more important than the ophthalmic condition. A regimen—the very reverse probably of that which the child has undergone—must be instituted for the improvement of nutrition, and thereby arrest the disintegrative process going on in the cornea. Air, exercise, and plain nutritious food; with iron, quinine and cod-liver oil, as medicinal measures; comprise the elements of the antiscrofulous course of treatment. The bowels will have to be well regulated, as part of the treatment of the scrofulous constitution, and in consequence of the constipating influence of iron. Further particulars respecting the most eligible preparations of the medicinal agents adverted to, were noticed in the general treatment of SCROFULA. Of topical applications; a weak astringent lotion of alum, two or three grains to the ounce of water, is perhaps the most efficacious; and warm poppy-head fomentations or the vapour of laudanum will most effectually relieve the distressing intolerance of light. A green shade should be worn to shield the eyes. A small blister may be applied to the temple, and repeated in a week or ten

days; but there is little need of derivation. Spermaceti, or dilute citrine ointment, may be smeared along the edges of the lids at bed-time; in the advanced stage of the disease. Of local applications *not* to be used; Mr. Dixon especially denounces the nitrate of silver, and lead lotion whenever an ulcer exists—the carbonate of lead being precipitated and forming an insoluble white deposit in the cicatrix.

Opacity of the cornea, resulting from cicatrization, remains more or less permanently after a prolonged attack of scrofulous ophthalmia; but this result gradually wears out in after years, and at length a faint trace only may indicate the site of the cicatrix.

*Granular Conjunctiva*—is a serious consequence of purulent ophthalmia in any form, or of a long continued course of irritant applications. A thickened, and rough state of the conjunctiva is thus produced; and particularly of the palpebral conjunctiva, which, when examined, appears villous, and resembles the surface of a granulating ulcer. The villous projections are, however, the follicles and papillæ of the conjunctiva, enlarged by inflammatory deposit: and acquiring considerable solidity and hardness, they irritate the ocular conjunctiva, especially its upper half, occasioning lachrymation and blinking of the lids. By constant attrition, an opaque and vascular state of the cornea ensues, having an almost fleshy aspect—*pannus*. Granular conjunctiva, as consequent on purulent ophthalmia, is common among the more destitute Irish population.

*Treatment*.—Remedial measures have for their object the removal of the granular state of the conjunctiva. The palpebral conjunctiva has been subjected to the rapid action of escharotics, as by the free application of nitrate of silver; or removed, by paring it with a fine knife or scissors. The best applications are; the acetate of lead in fine powder, dusted over the everted lid, which acts probably as an astringent; or the undiluted liquor potassæ dabbed on the everted lid, may be a more effectual application, probably by chemically saponifying and dissolving the granular-hypertrophied tissue. Repeated at intervals of a few days, for six or seven weeks; the granulations will probably disappear, and the transparency of the cornea be considerably restored. Counter-irritation, by means of small blisters on the temple, or the tincture of iodine painted over the skin of the lids, seems to aid this result. In obstinate and otherwise intractable cases, it has been proposed to resort to *inoculation*, for the reproduction of purulent ophthalmia—by applying to the conjunctiva the purulent secretion from the eye of a patient suffering under the acute form of that disease. This desperate remedy has sometimes produced a perforating ulcer of the cornea; but sometimes considerable clearing of an opaque cornea, without any ulceration. It seems reasonable, therefore, to reserve this resource to the last. The general treatment is always most important; tonics and a nutritious diet have a constitutionally curative influence, without which any local measures are powerless.

(2) Certain GROWTHS of the conjunctiva, require notice.—*Pterygium* is a reddish, fleshy, fibrous growth of the conjunctiva, of a triangular shape; extending, base inwards, from the semilunar fold at the inner canthus to the cornea, or beyond its margin.

It occurs mostly in persons who have lived in hot climates, and exposure to dust may be an exciting cause.

The *treatment* is excision. The lids being held apart with a spring speculum, the growth should be seized with tenaculum forceps, close to

the cornea, and dissected carefully off the sclerotic towards the inner canthus; avoiding the caruncle and semilunar fold. Any small portion remaining on the cornea had better not be meddled with, although as obstructing the vision, its removal is all-important. But it will probably wither and disappear. If removed by operation, this portion of the pterygium can be more safely excised by a small pair of curved scissors.

*Pinguecula*, signifies small yellowish elevations on the sclerotic, close to the margin of the cornea. Supposed to be fatty, they consist chiefly of fibrous tissue. They form after the middle period of life, and especially in persons who have been much exposed to the weather, or have lived in hot climates.

These little masses are quite harmless, and had better be left alone.

*Tumours*, such as occur in other parts of the body, may also spring from the conjunctiva. Warty and polypoid growths occasionally arise from this membrane. Early excision, is the only remedy. Fatty tumour sometimes forms *under* the conjunctiva, in the sub-conjunctival tissue. Mr. Dixon has seen a few such cases, in children; the tumours all occupied the same position—the line of reflection of the conjunctiva from the lower lid to the globe. They extended from near the lower edge of the cornea to the outer canthus, were elongated in shape, almost like a haricot bean, and partly concealed by the lower lid. An incision through the conjunctiva and fibrous capsule of the tumour, readily allowed the fatty mass to be turned out.

*Cysticercus telæ cellulosa*.—This parasite is found, very rarely, in the sub-conjunctival cellular tissue. It appears as a rounded body, about the size of a pea; situated midway between the inner canthus and cornea in two instances. A slight incision lets this body slip out. Its nature will be shown by examination under the microscope.

*Stains from Nitrate of Silver*.—A dirty sepia tint of the sclerotic is apt to follow the prolonged application of nitrate of silver, as an eye-wash. In one case, Mr. Dixon found that the stain almost disappeared under the long continued application of hyposulphite of soda in solution, ten grains, gradually increased to a drachm, to the ounce of water. It is necessary to maintain the contact of the solution for some time; and this was accomplished by means of an eye-glass, the patient being ordered to draw down the lower lid and fix it against the cheek-bone with the rim of the glass, before reclining his head.

DISEASES OF THE CORNEA.—(1) CORNEITIS OR KERATITIS.—Inflammation of the cornea is denoted by crescentic vascularity, passing from the edge of the cornea for some little distance into its substance. This characteristic vascularity involves a third or half of the corneal circumference, and the constituent plexus of vessels is so fine that it appears as a small patch of blood smeared upon the surface of the cornea. An inch focus glass will, however, show the vessels composing the plexus. A zone of pink vessels in the sclerotic, surrounds the cornea; but this is present also in iritis and other deep inflammations of the eye. Conjunctival vascularity, indicative of ophthalmia, is absent. Profuse lachrymation and intolerance of light accompany corneitis, as in other affections already described. Haziness and opacity of the cornea soon supervene; eventually, softening with a yellow tint, ulceration of the cornea, and suppuration within its substance, or, the matter bursting through the cornea posteriorly sinks down to the bottom of the anterior chamber—*hypopyon*.

ensues. One eye usually suffers and then the other, perhaps as the first is recovering.

Children are most liable, and the disease rarely occurs after the age of twenty. The constitutional condition is generally weakly, and the subjects anæmic and pale. There may be marks of scrofula.

*Treatment.*—No lowering measures are tolerated. The remedial measures, local and general, so entirely resemble those of Scrofulous Ophthalmia, that any repetition is unnecessary.

*Chronic Interstitial Keratitis*—so named by Mr. Hutchinson, has been shown by him to be a manifestation of inherited constitutional syphilis. Presenting itself in children and young persons from five to eighteen years of age, this form of corneitis may be recognised by the following appearances. It begins at the centre of one cornea, as a diffused haziness like that of ground glass. Whitish dots soon beset this haze, forming in the very substance of the cornea. Coalescing, they increase the central opacity. A fine plexus of vessels now overspreads the cornea, deeply pervading the opaque portion; and especially affecting the upper and central part, rather than the lower half, of the cornea. There is no tendency to ulceration. Subsequently, in about two months or earlier, the other cornea undergoes the same form of opacity and vascularity, in like manner.

*Diagnosis.*—The vascularity will be observed to differ from the lash of vessels in scrofulous ophthalmia, and from the superficial crescentic plexus of ordinary corneitis. Other marks of hereditary constitutional syphilis accompany this affection of the cornea, and particularly a certain characteristic vertical notching of the upper central incisor teeth.\*

The *treatment* recommended is a combined specific and tonic plan, consisting of mercurials and iodides, supported by tonics and a nutritious diet.

*Opacities of the Cornea.*—These conditions have been noticed incidentally as consequences of various affections of, or involving, the cornea. Corneal opacities are of two kinds—simple opacity, resulting from inflammatory disintegration and interstitial deposit—*e.g.*, *nebula*; and cicatricial opacity, resulting from ulceration, with loss of substance, and cicatrization—*e.g.*, *albugo*, and *leucoma*. The former state of opacity may be simple haziness, and comparatively transient; the latter is a more dense, white opacity, and probably permanent.

But the prognosis will depend very much on the age of the patient. In infancy and youth, when nutritive changes are most active, cicatrices of even large size diminish both in extent and density, until the cornea becomes almost clear in after-life.

*Treatment.*—Practically, the distinctions adverted to are most important, simple opacity being curable, cicatricial opacity incurable, by art. Any treatment can only be curative by promoting the molecular changes of absorption and nutrition. To this end, weak stimulant washes to the eye, and a generally tonic and dietetic course of treatment may contribute. The curative influence of mercurials is doubtful.

*Ulcers of the Cornea.*—The characters of these conditions have been sufficiently described in connexion with Purulent and Scrofulous Ophthalmia, and Corneitis.

*Treatment.*—Nutrition must be promoted by tonics and diet. Of local

\* Ophthalmic Hospital Reports, vol. i. 1858, and Trans. Path. Soc. vol. ix.

stimulant applications, by eye-drops or eye-washes, nitrate of silver is the most efficacious adjunct to the general treatment. Its use should not be continued too long, lest an insoluble deposit taking place in the ulcer, opacity may result. Lead-lotions, on this account, are wholly inadmissible.

*Staphyloma*.—Protrusion of the cornea, probably involving the iris, results whenever the cornea, in whole or in part, has been destroyed by injury or disease, and a cicatrix having formed, it there bulges forwards before the pressure of the humours of the globe; presenting an opaque white prominence.

*Treatment* should be directed to the arrest of such projection. Nitrate of silver applied to its apex may induce just sufficient inflammatory deposit to thicken and strengthen the yielding cornea. A small, conical, staphyloma, not involving the iris, may be shaved off; cicatrization will then, perhaps, brace up the cornea and prevent any further protrusion.

(2) *CONICAL CORNEA*.—A rare deformity, in which the cornea has become extremely convex, but retains its transparency, and gives a remarkably brilliant appearance to the eye. The conical shape of the cornea is well seen in profile. Dissection, in a few cases, has shown that the apex of the cone is very much thinned. The position and movements of the iris remain unchanged, and the other tissues of the eye unaffected. But the patient—usually between twenty and thirty—grows short-sighted, and at last becomes totally blind.

*Treatment*.—All kinds of operative measures and eye-washes have been tried and failed. The only relief has been found in compensating optical contrivances. Deeply-concave glasses enable the patient to see, in slight cases. A small, pin-hole aperture, in a blackened shield, or metallic plate, held close to the eye, will enable a patient to read at a focus of five or six inches, who could not otherwise discern a letter. Or, a slit, about three-fourths of an inch long, and the thirtieth of an inch wide, allows a considerable range of lateral vision, without moving the head. A combination of concave glasses and this perforated diaphragm, set in a spectacle frame, may prove even more advantageous.

(3) *ARCUS SENILIS*.—A circumferential opacity of the cornea, depending, as Mr. Canton has shown, on fatty degeneration. When both eyes are affected, this opacity denotes one of those naturally degenerative changes of nutrition, which the cornea, in common with other textures—especially those of low vitality—undergo as life advances, say from fifty years of age, onwards. Thus, arcus senilis is often associated with fatty degeneration of the heart. In like manner it may be indicative of premature old age. As affecting one eye, it is generally the result of previous injury or disease of the organ itself. Fortunately, this textural deterioration does not interfere with vision, nor render the texture of the cornea unfit for operation, as the extraction of cataract—the wound then uniting quickly and soundly.

No known *treatment* is of any avail.

*DISEASES OF THE SCLEROTIC*. — *SCLEROTITIS*. — Inflammation of the Sclerotic, or white coat of the eye, has been alluded to as occurring *partially*, in connexion with Catarrhal Conjunctivitis, and with Corneitis, and it also accompanies Iritis. The vascular contiguity or continuity of the textures severally affected with Inflammation, probably explains this concurrence. But Sclerotitis may occur alone, or at least as a primary affection, and more completely than when thus associated.

The whole of the sclerotic is intensely injected, the otherwise white coat assuming a pink tint, shading into violet, owing to the depth of the vessels in the fibrous tissue. Lachrymation and intolerance of light are marked symptoms; and pain deep-seated in and around the eyeball, of an aching and neuralgic character, radiating to the brow, temple, and cheek, and penetrating to the back of the head. Exacerbations occur during the night, and remit towards morning. The constitutional disturbance, also, is intense, the febrile symptoms leading to a copious deposit of lithates in the urine; hence the disease has been named *Rheumatic Ophthalmia*.

*Diagnosis* from Conjunctivitis.—The redness differs in its colour, being a pale pink, and the injected vessels run in straight lines from the circumference of the eye towards the cornea; whereas, in conjunctivitis, the colour is crimson, the vessels tortuous and anastomotic, forming an open network, which, moreover, can be moved about under the finger. The intense, deep-seated pain of scleritis, compared with the pricking sensation as of a grain of sand in the eye, will confirm the diagnosis.

*Treatment*.—A free purgation should be followed by opiates, in narcotic doses. Quinine is valuable in proportion to the neuralgic character of the pain; and colchicum with an alkali or iodide of potassium, according to the rheumatic character of the constitutional disturbance. Dover's powder is then a suitable narcotic, its sudorific influence also proving beneficial. In point of diet, sugar and sugar-forming substances are forbidden.

Local measures seem to be comparatively useless for subduing the inflammation; bleeding, by means of leeches, gives only temporary relief, and blistering aggravates the neuralgia. Steaming the eyes with warm water may afford soothing comfort, or friction of the forehead every afternoon with extract of belladonna dissolved in warm laudanum, a drachm to the ounce; or dry warmth by means of muslin bags filled with camomile flowers, heated on a plate. But perhaps the most soothing application is chloroform, diluted with olive oil, on lint, applied to the temple and forehead. The patient's room should be moderately darkened, and an eye-shade worn.

*Chronic scleritis* does not affect the whole of the sclerotic coat at once, but appears as a limited patch of redness, close to the cornea; this fading away, it reappears elsewhere, always close to the cornea. Eventually, the cornea or iris may become involved, thus inducing opacity, or a very insidious iritis.

*Treatment* consists in the same remedial measures and observance of diet, as in the acute form of scleritis; but this plan of treatment must be pursued more or less for a long time. Any tendency to opacity of the cornea, or iritis, must be checked in limine; calomel and opium being administered in small doses, while the circulation is sustained by bark and nutritious food.

**THE ANTERIOR CHAMBER.**—A living *entozoon*—the *cysticercus telæ celulosæ*, has not unfrequently been found in this situation. It is a rounded, semi-transparent, vesicular, body, having a long, retractile, neck, terminating in a head furnished with suckers and a circlet of hooks. As a foreign body, it excites inflammation of the iris and cornea, ending in total blindness. A crescentic incision along the margin of the cornea, lets out the animal with the aqueous humour. Perfect rest and protection from light should then be secured during the process of healing. A

bandage, therefore, is worn over both eyes for the first twenty-four hours, and afterwards the wounded eye should still be kept closed as the incision unites and the aqueous humour is re-secreted. Any constitutional management will be suggested by the irritability, weakness, or other state of the patient.

**DISEASES OF THE IRIS.**—(1) **IRITIS.**—Inflammation of the iris presents certain characteristic appearances—chiefly a loss of the peculiar fibrous texture of the iris, a change of colour, from dark to reddish or from blue to greenish, diminished size, and an irregular shape of the pupil, and early loss of its mobility, with a well-marked sclerotic zone around the cornea. Sometimes, the conjunctiva becoming involved, it also is injected; or the cornea appears slightly hazy. Intolerance of light is a symptom common to other ophthalmic affections; and deep-seated, radiating, and paroxysmal pain occurs, as in scleritis

Lymph is effused, producing further changes in the appearance of the iris; its surface acquires a rusty, villous or nodular aspect, adhesions take place forwards to the cornea, or backwards to the capsule of the lens. Sometimes, the pupil becomes occluded with a film of lymph, and the anterior chamber may be occupied by a more abundant effusion. The accompanying impairment of vision is proportionate in its completeness and probable permanency. But, in iritis, the *retina* is often more seriously affected than the iris itself; and this concomitant disease has been discovered by the ophthalmoscope.

*Causes.*—Iritis may have a traumatic origin, as a consequence of various injuries of the eye, or of its over-functional exertion; or the disease may be a local manifestation of various constitutional conditions—secondary syphilis, rheumatism, gout, or scrofula. One, or both eyes may be affected; in the former case by injury; in the latter, by constitutional disease. But in some such cases, both eyes are attacked simultaneously or in succession, and occasionally the disease is limited to one eye; or relapses occurring, the eyes may be affected alternately. These manifestations of constitutional disease are all illustrated by Syphilitic Iritis.

*Varieties of Iritis.*—Inflammation of the iris varies, like other diseases, in its intensity and duration, whereby it is distinguished as the *acute* and *chronic* forms of iritis. But its modifications correspond also, and more particularly, to the constitutionally-causative conditions: thence, the syphilitic, rheumatic or gouty, and scrofulous, forms of Iritis. Their symptomatic distinctions are far less definite and characteristic.

(a) *Syphilitic Iritis.*—Lymph-effusion is the most marked feature, taking place rapidly and abundantly; *nodules* of lymph are presented, of a yellow, reddish-yellow, or nearly red colour, and situated especially about the edge of the pupil, encroaching upon or even occluding the pupillary area. The cornea often remains perfectly transparent, even when the iritis is most severe. On the other hand, those symptoms which more peculiarly accompany rheumatic iritis, are absent—a generally-diffused redness of the sclerotic, and great intolerance of light.

*Diagnosis.*—But the nodular appearance of lymph is so uncertain, as to render its diagnostic value very doubtful. Thus, the lymph may be uniformly distributed around the margin of the pupil, which then assumes a thickened ring-like appearance; the rest of the iris retaining almost or altogether, its healthy aspect. Occasionally, nodules of lymph, instead of forming on the edge of the pupil, are situated on the circumference of the iris, adjoining the cornea. Other secondary syphilitic affections of

the throat or skin, are usually present with, or have preceded, the iritis. This concurrence is far more surely diagnostic.

(b) *Rheumatic Iritis*.—A general diffused redness of the sclerotic, as the most marked appearance, and great intolerance of light, with orbital radiating and neuralgic pain, are the most characteristic symptoms. The cornea is almost always hazy. But the nodular form of lymph deposit is absent, and effusion takes place so sparingly and insidiously; that the morbid changes in the iris, thus slightly marked, may escape observation, in the first instance. When the inflammation has subsided, and the cornea become clear, irremediable adhesion of the iris may then be discovered.

The disease seems plainly of rheumatic origin, and is frequently associated with other rheumatic affections.

(c) *Scrofulous Iritis*.—The ocular appearances have a general resemblance to those of syphilitic iritis; in the abundant deposit of nodular masses of yellowish lymph, but situated more frequently midway between the pupil and the circumference of the iris, or at this part. Slight hæmorrhage, not uncommonly, takes place into the anterior chamber, from bursting of the distended veins of the iris. The cornea usually remains clear.

*Treatment*.—Iritis presents certain *general* indications of treatment; irrespective of whatever form it may assume. They are; to arrest inflammatory effusion, and promote absorption of any lymph-deposit; and to prevent adhesion of the iris; also, to relieve pain. The constitutional treatment will be that of inflammatory fever.

To *arrest inflammatory effusion*; bleeding by leeches or cupping to the temple, followed by blisters, must be maintained by temporary laxative aperients and low diet. Mercury seems to have the power of arresting the effusion of lymph, far more than of inducing its *absorption*. Calomel and opium may be administered, in small doses—say a grain or two with a quarter of a grain respectively, every four or six hours; its influence on the eye being watched, rather than with the view to salivation. Other preparations of mercury, such as hydrarg. c. cretâ, may be given, in like manner. Tonics, principally quinine, and a nutritious diet, must soon replace any general lowering measures; thus to re-enforce absorption, by maintaining the circulation.

To *prevent adhesion* of the iris, posteriorly, to the capsule of the lens, or anteriorly, to the cornea; belladonna has the most powerful influence, applied topically, as a means of dilating the pupil and keeping it in that state, removed from the liability of contact. The extract may be smeared around the eye, or a solution of the extract, one scruple in an ounce of distilled water, may be dropped into the eye, occasionally. The sulphate of atropine—a grain to the ounce of water, forms a solution of greater value. Mr. Dixon regards atropine—or belladonna—as inert and useless during the acute stage of iritis; but that it may be advantageously applied when the inflammation has subsided, and the iris is beginning to regain its contractility—as the means of then ascertaining the extent of adhesion.

To *relieve pain*; steaming the eye over hot water is a most soothing application, or neuralgic orbital pain, sometimes involving the three divisions of the fifth nerve, a most severe affection, may be relieved by friction with warm laudanum to the forehead and temple.

*Syphilitic* iritis should be subjected to the same plan of treatment. But, the effusion of lymph being particularly rapid and abundant.

mercury should be pushed more freely. Turpentine was recommended by Carmichael, as a substitute for mercury, in cases of great general debility. Its efficacy is very uncertain. Iodide of potassium with bark will probably be found more suitable.

*Rheumatic* iritis, requires the administration of mercury in small doses, to check the insidious effusion of lymph; turpentine in pill, four grains thrice a day, is most effectual in subduing the iritis, when characterized by visible injection of the iris and sclerotic, without much disposition to lymph-effusion. Some more specific treatment will also be appropriate; colchicum and alkali, or iodide of potassium. The neuralgic pain must be relieved, as already directed. Blisters will probably aggravate its severity.

*Scrofulous* iritis is more specially amenable to the general treatment of other manifestations of Scrofula. Quinine, iron, and cod-liver oil, as the chief remedial measures, must be reinforced by careful regulation of the digestive organs, and a regimen—comprising pure air, daily exercise, warm clothing, and a plain nutritious diet. Local treatment is of little avail.

ADHESIONS OF THE IRIS.—*Synechia posterior*, adhesion of the uvea to the capsule of the lens; *synechia anterior*, adhesion of the iris to the cornea; and *Atresia iridis*, closure of the pupil; are three conditions resulting from prolonged iritis.

The *treatment* consists in the application of belladonna or atropine, as a safeguard against any further adhesion, thus to preserve even a partial pupil; and the administration of mercury, in small doses, for some time, after recent adhesions. Established adhesions are curable only by operation.

*Staphyloma scleroticæ* is apt to follow synechia posterior and closure of the pupil with lymph. The aqueous humour secreted in the posterior chamber, being unable to pass through the pupil to the anterior chamber, continues to accumulate behind the iris; gradually bulging the iris, it also distends the anterior portion of the sclerotic; and this yielding forms a bluish-black prominence, streaked with the widely separated whitish sclerotic fibres.

(2) CYSTS OF THE IRIS are either congenital, or the result of injury by allowing the aqueous humour to find its way between the uvea and fibrous tissue of the iris. A cyst, thus situated, might be mistaken for a cysticercus or a dislocated lens; but it is principally distinguished by having a fixed attachment. An increasing cyst destroys the whole eyeball.

The *treatment* may be that of removal; by an incision through the cornea, withdrawing the cyst and cutting it off. Or—as Mr. Walton recommends—puncturing the cyst with an iris-knife, allows it to collapse. This operation may have to be repeated.

(3) MYOSIS and MYDRIASIS—signify, respectively, a persistent contraction or dilatation of the pupil; unconnected with any apparent structural disease of the part, and arising from purely functional causes. *Contraction*, sometimes occurs in persons accustomed to examine minute objects; and the iris refusing to dilate, this state is accompanied with impairment of vision, especially in a feeble light.

Rest of the over-used organ is the obvious indication of treatment.

*Dilatation*, is liable to occur from the over-application of belladonna to the eye, or the long-continued influence of narcotics. It may be caused

also by pressure affecting the brain, as in apoplexy and compression; and it is frequently symptomatic of confirmed amaurosis. It is said to depend, occasionally, on some eccentric source of irritation, as gastric irritation. Lastly, it may be symptomatic of an affection of the nerves supplying the iris, without any loss of sensibility of the retina; and this form is, perhaps, accompanied by ptosis, as a further symptom of paralysis of the third or motor-oculi nerve.

A tonic plan of *treatment* will, generally, be appropriate. Mr. Taylor recommends *nux vomica*; and derivation by means of a succession of blisters to the temple has proved beneficial, with the application of stimulating vapour, as of ammonia, to the eye. Improvement of vision—the retina retaining its sensibility—may be aided by habitually using concave glasses.

(4) ARTIFICIAL PUPIL.—*Operations* for the admission of light through the iris are of three kinds, all of which are comprised under the term, formation of an artificial pupil. (1) The formation of a new aperture in the iris, when the portion forming the natural pupil has prolapsed through a breach in the cornea; (2) the reopening or the enlargement of the natural pupil, when obstructed by inflammatory deposit; and (3) the displacement towards a transparent part of the cornea, of a pupil which has become concealed behind a dense corneal opacity.

The following *conditions* are laid down by Mr. Dixon as essentially necessary to be observed, before having recourse to any kind of operation for artificial pupil:—*Firstly*—whether the eye perceives light; mere obliteration of a pupil will not deprive the eye of this power, provided the retina be sound. *Secondly*—the presence or absence of the lens must, as far as possible, be ascertained; and, if present, whether it is transparent or opaque. *Thirdly*—the cornea must be carefully examined, as to its degree of transparency. *Fourthly*—the state of the iris. The existence of chronic iritis would indicate a postponement of the operation until inflammation has ceased. A thickened iris, in which all trace of its peculiar fibrous texture has disappeared, is specially unfitted for operation; as it breaks away under the slightest traction, and, if cut, the wound does not gape, so as to form a permanent aperture. *Fifthly*—as a rule, when the other eye is perfect, it is undesirable to operate.

The *situation* of an artificial pupil should be made as near the centre of the iris as circumstances will allow. The size of such pupil should not be unnecessarily large. Injury to the cornea should be as restricted as possible; the cicatrix encroaching on a cornea, which already has a limited area of transparency, will still further diminish the field of vision.

The different modes of making an artificial pupil may be arranged under four heads: laceration, incision, excision, and ligature of the iris.

*Laceration* consists in tearing away a certain portion of the iris from its ciliary attachment. An incision is made near the margin of the cornea, a sharp hook introduced, and carried across to the opposite side of the anterior chamber, it is there stuck into the iris, and then drawn back towards the corneal wound; then by rupturing the ciliary attachment of the iris to the extent necessary, the hook is detached and withdrawn. This operation, has however, been denounced as “unscientific, clumsy, and ineffectual,” and one which ought to become obsolete.

*Incision* is performed by means of a cutting-needle, or with scissors. The needle is introduced close to the edge of the cornea, and carried

across the anterior chamber to a little beyond the middle of the iris; the edge is then turned backwards, and the iris divided to the requisite extent. The instrument is rotated into its original position and withdrawn. Scissors may be used for dividing the iris—as proposed by Maunoir—but their introduction necessitates a large corneal wound, and neither a linear nor V-shaped incision can be easily accomplished when the iris is flaccid, by escape of all the aqueous humour.

The principle of this mode of forming an artificial pupil consists in utilizing the elasticity of the fibres of the iris; retraction immediately following their division, and thus the formation of an artificial pupil. The probability of success will, therefore, be proportionate to the tension and the healthy retractile power of the iris. But this operative procedure is contra-indicated by a contrary state of the iris, and by the presence of the lens behind, which will almost surely be injured by a cutting instrument. Hence, the operation is restricted in its application, to cases wherein, cataract having been extracted, prolapsus iridis has followed to such an extent as entirely to obliterate the pupil, and the iris is put on the stretch by its inclusion and union with the corneal cicatrix.

*Eccision.*—An opening having been made in the cornea, a forceps, or better, the blunt hook invented by Tyrrell, is introduced into the anterior chamber, a portion of iris is seized and drawn out of the corneal wound, and then removed with scissors. This mode of operation is specially appropriate in either of three conditions;—when, after extraction, extensive prolapse of the iris has ensued, so as to nearly obliterate the pupil; when, in consequence of iritis, the whole pupillary margin has become adherent to the capsule, the peripheral portion of the lens remaining transparent; when, the iris is perfectly healthy, but the pupil is concealed by a dense central opacity of the cornea, the remainder of the cornea retaining its transparency.

*Ligature.*—A puncture is made through the cornea for the introduction of a canula-forceps, a small portion of the iris near its ciliary attachment is seized, drawn out through the wound, and tied with a very fine silk thread. This transforms the pupil into an elongated slit. If this aperture be insufficient, it may afterwards be enlarged by ligature of a second portion of the iris, so as to draw the pupil into a triangular shape.

This operation—devised by Mr. Critchett, and named *Iriddesis*—limits the size of the pupil, and is applicable to a certain number of cases; as when prolapse of the iris has occurred, involving so much of the pupillary margin in the cicatrix, that the area of the pupil is reduced to a very minute aperture; or when the whole pupil has been displaced towards the extreme edge of the cornea, and there concealed by opacity.

*After-treatment of Artificial Pupil.*—In a tolerably healthy state of iris, the various modes of operation, if skilfully performed, are attended with little hæmorrhage into the anterior chamber, or inflammatory consequences. Repose of both eyes, by means of a bandage, is necessary for two or three days, and the operated eye should then be closed for a day or two more. At the end of a week, a large eye-shade will be sufficient, and tinted glasses should be worn for some time. Any opiates, and the regulation of diet, will be suggested by the constitutional state of the patient.

DISEASES OF THE LENS AND ITS CAPSULE.—CATARACT—is an opacity of

the crystalline lens or of its capsule, or of both; partial or complete. Agreeably to this definition, cataracts have been arranged under two primary forms: (1) Capsular cataract; (2) Lenticular cataract; or a combination of both, the most common form, (3) Capsulo-lenticular cataract. *Cortical* and *Nuclear* cataracts are terms proposed by Mr. Dixon, as synonymous with the two primary forms. *Lenticular* cataract again is distinguished according to its density, into the *hard* and *soft* varieties. These terms represent only certain stages in the progress of cataract; in no form of the disease does the lens undergo progressive hardening; but the lens for a long time retaining its naturally firm consistency while opacity is advancing, undergoes disintegration and softening, thus acquiring an uniformly whitish, milky opacity; eventually, perhaps, becoming transformed into a *fluid* condition.

*Symptoms, and Signs or Appearances of Opacity.*—Subjective symptoms, or those which the subject of the disease may himself experience, are not to be relied on as positive evidence; nor need such symptoms be accepted, since they can be *tested*, in regard to any functional defects of the organ. Dimness of sight, more or less marked, uniformly involving the field of vision, coming on gradually, without inflammation, and unattended with any impairment of motor power in the iris, is a suspicious symptom; but supposed defects of visual power should be tested and proved, by the independent observation of the Surgeon.

An examination of the suspected eye, or of both eyes, must be made; first, in its natural state, and afterwards, when the pupil is dilated by a few drops of the neutral sulphate of atropine,—two grains to the ounce of distilled water. A convex glass, of an inch focus power, should be used as a condenser, to concentrate light upon the surface of the lens; the patient standing in front of a window which admits a good light,—not direct sunlight.

*Capsular* cataract presents—behind the pupil—an opaque body, of a gray dead white colour; *Lenticular* cataract, a bluish-white or amber-coloured opacity. Various shapes and shades of opacity are recognised, of subordinate importance, but some of which may be noticed in connexion with cataract in adults and infants, respectively.

*Cataract in adults.*—Usually occurring in advanced life,—after the age of fifty or sixty; the rise and progress of cataract in elderly persons are as follows:—The circumference of the lens is first affected, commonly the lower edge, in the form of opaque striæ, which gradually advance along the posterior and anterior faces of the lens towards its axis. These striæ coalesce into patches, spreading chiefly over the posterior surface of the lens. In this state, the cataract may remain stationary for a year or several years. Then, the whole body of the lens, and especially the nucleus, becomes slightly hazy; through which, however, the posterior radiated opacity can be discerned,—the eye being illuminated with concentrated light. The anterior surface becomes involved, the opaque striæ advancing from the margin, until the points come within the area of the pupil. As the central opacity acquires greater density, vision is lost, excepting to strong light and bright colours. The fibrous structure of the lens gradually disappears with increasing opacity; disintegration proceeding, a deposit of earthy and fatty matter takes place, and crystals of cholesterine just within the capsule, may be recognised by their sparkling appearance. These further changes are limited to the surface of the lens, and present a *whitish* opacity. Sometimes they do not occur, and the

cataract has a dull *brownish* appearance like horn, very difficult of detection. *Black* cataract is a rare form of lenticular opacity.

*Fluid* cataract results from softening, beginning in the superficial portion of an opake lens, and involving the whole lens, until, in the course of years, it becomes converted into a thin pulp. The nucleus resisting this change may be surrounded with a turbid pulp of disintegrated tissue; a lens in this state constituting the "*Morgagnian* cataract."

*Congenital Cataract* presents various forms of opacity; the most common is that of an opaque nucleus, while the peripheral portion remains transparent. Other forms are, a small, white, central dot on the anterior face of the lens—*central* cataract, a diffused opacity occupying nearly the whole area of the pupil when contracted. This opacity projects forward in the shape of an obtuse white cone, which appears to adhere by its base to the anterior surface of the capsule—*pyramidal* cataract; and lastly, a very faintly striated opacity of the nucleus, a rare form of congenital cataract.

*Traumatic Cataract*.—In consequence of a blow on the eyeball, or a penetrating wound of the lens, the lens may become opake; the latter injury inevitably producing cataract. Disintegration and absorption of the lens ensue; the opake capsule remains. Iritis having been caused by the injury, the pupillary margin will probably be adherent to the capsule. Thus, then, an opake white disk occupies the area of the adherent pupil; but this disk is situated much further back than the position of a full-sized lens. Sometimes, other appearances are presented.

*Dislocation of the Lens into the Anterior Chamber*.—This injury may be conveniently noticed here. It occurs as a result of external violence, such as a blow upon the eye, or a violent fall. Disease may have pre-disposed, by weakening the suspensory ligament of the lens. This body may itself have become opake, when its appearance in the anterior chamber will at once be recognised. In a transparent state, the dislocated lens is remarkable; its margin exhibits the appearance of a ring of golden light. Pain and inflammation soon supervene. Prompt removal of the lens, through a suitable opening in the cornea, is the only treatment for saving the eye.

TREATMENT OF CATARACT.—No mode of cure, otherwise than by operation, is at present known; nor has any approach to a non-operative cure been discovered.

*Operations*.—(1) Extraction of the lens, by which the opaque lens is removed entire from the eye, through a suitable wound in the cornea. (2) Displacement of the lens; either by depression downwards, or reclination backwards, downwards, and a little outwards. "*Couching*," as this operation has been termed, displaces the lens from its natural position into an attitude such that, although remaining within the eye, it allows the rays of light to pass unimpeded through the pupil to the retina. (3) By Solution or Absorption. This operation consists, not in the "*division*" and breaking-up of the whole lens—a proceeding which still finds favour on the Continent, and was formerly practised in this country—but in the laceration of the capsule so as to expose the tissue of the lens to the macerating influence of the aqueous humour, whereby it undergoes complete absorption, a principle of operation established by Saunders, Tyrrell, and other English Surgeons.

*Extraction.*—The *instruments* required are these—a knife having a triangular blade; the back straight and blunt, the point sharp, the edge slanting obliquely and the blade increasing in thickness and breadth towards the handle—Beer's knife. A blade thus shaped occupies the incision in transfixing the cornea, and the semilunar-shaped incision can be made by simply an onward movement with the knife. A curette, or an instrument with a curved needle at one end, and a small spoon at the other. The guarded curette devised by Mr. Walton, is a safer form of this instrument. A sharp hook may also be requisite.

The directions to be remembered in performing the operation are as follow:—To make a crescentic incision in the cornea, through its upper half, and of sufficient size to afford an easy exit to the lens; to make the incision at such a distance from the sclerotic as to ensure both edges of the wound being wholly of corneal tissue; to lacerate the anterior capsule freely, so as to allow of the lens readily slipping through the rent when pressure is made on the globe; lastly, to apply this pressure, gently, in such manner that the lens shall turn slowly on its transverse axis, and thus present its upper margin first at the pupil and then at the corneal wound.

These directions are best fulfilled by the following mode of performing the operation of Extraction:—The patient lying on his back with the head supported, and in a good light; the Surgeon stands behind and uses his right hand for the right, and his left for the left eye. An assistant draws down the lower lid, and steadies it on the malar bone, without any pressure on the eyeball. The operator, with the point of his forefinger, raises the upper lid, locks it under the margin of the orbit, and by resting the point of that finger gently on the upper surface of the globe, and his middle finger against its inner surface, he steadies the eyeball. Holding the knife lightly between the thumb and first two fingers of the other hand, and resting the hand against the side of the face; he punctures the cornea at the centre of its outer margin, a *short distance in front of* its junction with the sclerotic, pushes the blade onward through the cornea, parallel with the iris, and transfixes the other side of the cornea, exactly opposite the external puncture. Owing to the triangular shape

FIG. 325.

of the blade, this incision forms an even semi-circular flap of the upper *half* of the cornea. (Fig. 325.) In making this cut, the blade must constantly fill up the wound, by a steady, onward, movement. If the knife be in the least withdrawn or rotated, a jet of aqueous humour takes place at that part of the wound which is no longer

occupied by the blade, and the iris immediately prolapses over its edge—a perilous juncture. Having completed the incision, the eyelids should be dropped, and all pressure instantly ceased. After a few seconds, the Surgeon again raises the upper lid, and introducing the curette, under the corneal flap and through the pupil, he *freely* lacerates the capsule of the lens, so that the rents shall extend quite across the area of the pupil. Lastly, very *gentle pressure* is made on the under and upper part of the globe, alter-

nately, whereby the lens turns slowly on its axis, and presents its upper edge at the pupil; coming forward to the cornea, the edge is guided upwards, and protruding, the lens escapes through the wound. During this transition of the lens forward, pressure on the globe should be gradually relaxed, lest the escape of the lens be followed by a gush of vitreous humour. The operation is concluded; but, after a short pause, the eye should be inspected to see that the iris is not prolapsed and that the cornea is adjusted.

*Complications.*—*Prolapsus of the iris* during the corneal incision may be rectified by slight pressure over it in completing the incision, or division of the fold of iris being unavoidable, the resulting aperture should be laid into one with the pupil by at once dividing the intervening strip of iris. An *insufficient* corneal incision must be enlarged by means of a short, narrow, blunt-pointed knife. A portion of the *lens* accidentally left behind, in situ, will be absorbed; or, from the anterior chamber, it can be easily removed by the scoop. Escape of the *vitreous humour*, resulting from an insufficient corneal wound and undue pressure on the eyeball, rupturing the hyaloid membrane, is attended with sinking down of the lens into the space left by the lost humour. Pressure must at once cease, and the lens be extracted by means of the scoop or hook entered *behind* that body, retained in position against the cornea lest it sink deeper into the vitreous humour. *Hæmorrhage* into the vitreous humour is the most dangerous complication of all. Severe pain in the eye, and oozing of blood from between the lids, soon proclaim the nature of this accident, but not until the whole cavity of the eyeball has become filled with blood. The sight is utterly lost.

*Conditions contra-indicating or unfavourable for, Extraction.*—(1) Extensive heart-disease is most unfavourable, by enfeebling the supply of blood necessary for reparative union of the cornea. (2) Violent cough of paroxysmal character, perils closure of the wound, and also prolapse of the iris. (3) Fat and flabby persons have less reparative power than thin and wiry, albeit old people. (4) Old age does not contra-indicate the operation; in one case Mr. Dixon operated on a gentleman of eighty-six, and four years afterwards he still enjoyed excellent health and good sight. Commonly, however, after seventy, the reparative power of the cornea is impaired. (5) If one eye only is affected with cataract, the other being free or nearly so, the operation should generally be deferred until vision is lost in both eyes. (6) If cataract be equally advanced in both eyes, and both appear equally suited for operation, it will generally be preferable to operate on only one eye at a time. Much may be learnt of value with regard to the second, by watching the first operation. (7) Extremes of hot and cold weather are unfavourable for the operation, and more especially sultry weather.

*After-treatment.*—The patient having been put to bed, with his shoulders somewhat raised, seclusion and darkening of the room are the circumstances most conducive to recovery. The wound of the cornea, protected by the lids, requires only to be covered with a piece of soft, dry, linen rag, lightly retained by a turn of bandage. The bowels should be kept easily opened, without straining or relaxation; and everything likely to excite coughing, sneezing, or vomiting, should be avoided. A moderate diet may be allowed. In from four to seven days, according to the probable reparative power, the eyelid may be raised, and the corneal wound and iris examined. All going on well, the patient may be allowed

to move about a little; and at the end of another week, if union be sound, the eye may be opened in a weak light, and gradually brought into use. Any exposure to a strong light, or cold, or over-use of the eye, must be avoided. A shade should be worn, and a convex glass used, but it will be difficult to make the two eyes act in harmony.

Inflammation after the operation has been always a great bugbear. But, in a healthy subject, and after a skilful operation, the cornea unites, without inflammation, almost as readily as other soft textures. The state of the eyelids and secretion will indicate the supervention of inflammation, and the necessity for any antiphlogistic measures.

Very rarely, a fistulous wound results, and proves most troublesome. The aqueous humour constantly draining away, the anterior chamber becomes obliterated and the iris lies in contact with the cornea. When this state has existed for several years, all useful vision will be lost.

*Displacement or Couching.*—This operation for cataract is performed by introducing a curved needle through the sclerotic, just behind the margin of the cornea, and in the transverse axis of the globe; penetrating the vitreous humour, the posterior aspect of the capsule of the lens is

FIG. 326.

lacerated with the point of the needle, which is then carried upwards and forwards behind the iris to the front of the cataract, and the lens gently and steadily depressed downwards into the vitreous humour, until it is carried out of sight. (Fig. 326.) There having been held for a few seconds to fix it in its bed, the needle is withdrawn.

*Reclination*—a modification of depression, is performed in like manner; the lens being reverted backwards, downwards, and a little outwards. For either mode of this operation, the pupil should be dilated by a few drops of the solution of atropine, applied about an hour previously.

Displacement of the lens has all the attractive advantages; of simplicity, rapidity, and immediate restoration to sight. But, the chance of some structure essential to vision being injured by a wound in the dark during the operation; or of inflammation supervening in consequence of the lens, as a foreign body, sinking further down on to the retina, or falling forwards against the ciliary processes and iris; make a sum total of accidents adverse to this procedure.

The conditions favourable for displacement, are such hard cataracts as may not be suitable for extraction.

*Operation for Solution and Absorption.*—The pupil being well dilated, the needle is introduced through the cornea, close to its junction with the sclerotic, and thrust onwards until its point reaches the centre of the pupil. Then, the anterior capsule is to be freely lacerated in various directions, and the body of the lens broken up; and the needle may be carefully passed quite through it, so as to lacerate the posterior capsule.

Two needles may be used together, in order to more effectually tear the extensible texture of the capsule; but the one should be passed in

until its point reaches the middle of the pupil, before the second one is introduced through the cornea.

This operation is suitable for *soft* cataracts, especially the congenital in infants; but it is not appropriate for hard cataracts, in old people.

Both eyes may be operated on simultaneously, in infants; but one eye, that most affected, should be operated on first, in adults.

A *fluid* cataract having been subjected to solution by the needle; distressing sickness and perhaps intense neuralgia, almost invariably sets in immediately. The anterior chamber is full of creamy fluid, concealing the iris. On evacuating this fluid, by means of a broad cutting-needle introduced at the point of puncture, the sickness may be averted. Nausea is best relieved by swallowing fragments of ice, and the neuralgia by chloroform liniment applied to the forehead and temple.

The *after-treatment* is simple; both eyes should be kept closed by means of a light bandage for twenty-four hours; when the little puncture wounds in the cornea will have closed. A single operation may suffice to procure absorption, in the course of a few weeks, but this is a rare result; usually, it must be repeated again, and a third time, at an interval of two or three months.

An *Opake Capsule* or *Capsular Cataract*, remaining after the operation for solution, must itself be removed. This can be done by either of three operations. (1) A needle may be introduced as for depression, and the opake capsule torn through; as it shrinks away, the pupil becomes clear. (2) The upper part of the capsule, for four-fifths of its circumference, may be detached by the needle from the suspensory ligament, and then be pushed down below the pupil. (3) These operations having failed, an opening may be made in the cornea, through which the opake capsule is extracted by means of a small hook or forceps. The latter instrument should be so constructed that when its points are separated, the iris shall not fall between them. Such is the canula-forceps.

OPERATIONS ON INFANTS.—Congenital cataracts should be operated on at an early period—within four months after birth; otherwise, the eye born blind, constantly oscillating from side to side, may never acquire directed vision. The child having been swathed in a long towel, and reclining, under the influence of chloroform; the head is steadied by an assistant, and the operation for *solution* performed. The lens is so soft, that this procedure may be completed at once, and on both eyes. A bandage is then applied. Inflammation rarely supervenes, and absorption takes place rapidly.

DISEASES OF THE CHOROID AND RETINA.—(1) *Inflammation* of the Choroid and Retina, respectively, long held a recognised position in Ophthalmic works; the terms, *Choroiditis* and *Retinitis* signifying definite inflammatory diseases of these structures, and each having its own distinctive symptoms. But, in exploring the recess of the eyeball behind the lens, by means of the Ophthalmoscope, the appearances brought to light have not established any such distinctive inflammatory affections; nor as diseases existing independently of other deep-seated inflammation of the eyeball. Deep-seated inflammation has already been sufficiently noticed in connexion with Scleritis and Iritis. "Congestion" of the Choroid, is a mere pathological refinement, of even more doubtful existence, and has no special practical significance.

(2) *Dimness* of sight, may be symptomatic of *various* deep-seated

morbid alterations in the eyeball; unconnected with any changes in the anterior tissues of the globe, and as discovered by external examination with the unaided vision. Thus, the Ophthalmoscope may show masses of pigmentary deposit overspreading the choroidal surface, or an inflammatory state of the choroid, in common with nearly every tissue of the eyeball.

(3) *Defective sight*, in various forms, is apparently unconnected with any morbid state of the choroid or retina, as examined by the Ophthalmoscope; although these functional defects are commonly attributed to structural changes in one or other of these tissues.

(a) *Impaired vision*—or weak sight is a defective sight for near objects. It occurs mostly in those persons who are accustomed to use their eyes much in looking at minute objects. Thus, jewellers, watchmakers, copying clerks, tailors and needlewomen are the common subjects of this affection. Yet it also occurs in those who follow no such occupations, but whose age is that of the turning period of life; say, approaching fifty. At first, small objects or small type, are seen clearly, but in a few minutes they grow indistinct. A moment's closure of the eyes restores the power of vision. The work or type again becomes misty, and the effort to see is discontinued. Larger type will enable a reader to continue reading for a while, but ultimately this can be seen with difficulty, especially in artificial light. The *cause* of defective sight would seem to be a failure of the power of adjustment, due probably to a loss of contractility in the ciliary muscle.

The *treatment* certainly should have reference to the condition as an optical disarrangement, and not to any supposed congestion of the choroid, or disordered digestion.

Convex glasses should be used, of suitable convexity; the lowest powers being tried first, so as to see without strain or effort.

(b) *Musæ Volitantes*.—Little black objects are sometimes seen to fall or float over the field of vision, when the eye is fixed; a sudden turn of the eye will disperse them for a moment, again to reappear. Steady concentration of the vision on any external object, obliterates these black specks, but any slight alteration of the focus of adjustment, brings one perhaps into view, and immediately the whole field of vision becomes crowded with them. They may be seen and moving freely, when the lids are closed, if the eyes be turned towards a strong light. These small, black, moving objects are not due to congested vessels of the choroid, although their real nature has hitherto escaped detection. They move freely in a fluid, through a limited space, and probably near to the retina. The surface of the cornea is not the sphere of action, as proved by their position remaining unaffected in blinking of the eyelids.

Musæ occur commonly in short-sighted persons, usually commencing to appear between the ages of 20 and 30; and having attracted the patient's attention, they seem rapidly to increase in number, owing partly to the habit acquired of bringing fresh bodies into focus. Their presence is quite compatible with excellent and life-long sight. But, they are *incurable*.

AMAUROSIS.—This term, signifying simply dimness of sight, proceeding perhaps to total blindness of one or both eyes, is thus far a functional condition; but the loss of vision is dependent on, and symptomatic of, various structural changes in the retina or choroid, the optic nerve or brain. Some such changes, therefore, are open to examination with the

ophthalmoscope, while others are concealed and must remain hidden within the cranial cavity.

*Ophthalmoscopic Appearances.*—The principal morbid appearances or conditions, as shown by examination of the interior of the eye with the Ophthalmoscope, are:—a *dusky halo* around the optic nerve, commonly attended with general dimness of sight in a slight degree, *amblyopia*; a *white patch* of variable extent and very irregular outline, immediately surrounding the optic nerve; *yellowish-white* spots scattered over the retina, in dimness of sight with Bright's disease; *black pigment* deposits on the retina; a round white patch of exposed *sclerotic*, fringed with a black margin of pigment; *extravasations of blood*, either from the choroid or retina, presenting, after a time, a slight brownish stain, a faint mottling, a linear or stellated cicatricial appearance of a lighter colour than the surrounding tissue. *Serous effusion* between the retina and choroid may occur as a result of acute or chronic inflammation. The acute form of effusion is part of that general disorganization, involving every tissue, of the eyeball, which constitutes *glaucoma*. Chronic effusion may exist in such a small quantity as merely to impart a cloudy appearance to a limited portion of retina; or, it may have detached a considerable extent or the whole of it from the choroid. Limited effusion occurs frequently in the immediate neighbourhood of the optic nerve; appearing as cloudy grayish patches in the midst of healthy tissue, the radiating vessels spread over the rest of the fundus being lost at the edge of the patch. Alteration of focus will bring these vessels into view over the patch. A large extent, or almost the entire retina, having become detached by effusion, presents an opaque grayish surface, or the whole fundus of the eye; which contrasts with the reddish reflecting surface of any undetached portion of retina.

The *optic nerve* at its ocular extremity, may present changes of size, form, and colour, peculiar to itself. But very great variations are compatible with good sight. Certain natural changes incident to advancing life, are—shrinking and deviation from the circular form, with a darkening of colour approaching to gray. Other changes are morbid, though not necessarily of much consequence in respect to vision. *Black pigment* is frequently seen in the form of a thin line around the optic nerve, to the extent of a sixth or a quarter of its circumference. *Degeneration* and atrophy of the nerve, with chronic congestion of the retina, are characterized by ivory whiteness of the one, and a uniform red colour of the other. This combination of appearances is presented in connexion with blindness from cerebral disease involving the optic nerve. *Pitting*, or indentation of the extremity of the nerve, has recently been noticed, in certain cases of greatly-impaired or lost vision. This concave appearance having also been met with in glaucoma, it has been attributed to intra-ocular pressure from over-distension of the eyeball; but it is more probably the result of atrophy and consequent shrinking of the nerve-tubules. Several of the preceding structural changes are, therefore, apparently due to atrophy of either the retina or the optic nerve—*e.g.*, white patches on the retina of old persons, the dense white optic nerve accompanying intra-cranial disease of the optic apparatus, and concave indentation of the nerve, in slowly-advancing blindness. Atrophy of the *whole retina and optic nerve*, without any previous inflammatory process, may also occur. The choroidal vessels are so clearly seen that the retina seems altogether absent; the optic nerve is small, shrunken, irregular in outline, of a dark gray or

drab colour, and the vessels emerging from it form delicate, hair-like, red lines, barely seen across the area of the choroid. Sometimes, the choroidal vessels have undergone a remarkable change of colour; being pale, orange, or buff, instead of red. This general condition of atrophy occurs chiefly in old people; vision gradually fades away year by year, mere perception of light alone remaining at the last. It has been mistaken for steadily-advancing cataract. Ophthalmoscopic examination alone reveals the true nature of this change—a form of amaurosis.

*Symptoms.*—Dimness of vision is the essential symptom in amaurosis, but experienced and manifested in various ways. Coming on suddenly or gradually, and sometimes better, sometimes worse; there may be a general indistinctness of vision—*amblyopia*; or objects appear double—*diplopia*; or half only of an object is seen—*hemipopia*; or objects appear bent, disfigured, or discoloured, or patched. Distances cannot be estimated, and therefore the individual misses his aim in trying to snuff a candle, or pour wine into a glass. The flame of a candle appears split, elongated, or scattered into a brilliant halo. *Ocular spectra* of various kinds make their appearance; sparks, flashes of phosphorescent clouds, or dark spots—*muscæ volitantes*, may be seen when the eyes are turned towards light-coloured surfaces. Great *intolerance of light*, or perhaps longing for light, is sometimes experienced.

These subjective appearances or sensations may be premonitory symptoms of amaurosis.

The pupil is generally dilated, except there be intolerance of light, and the iris is sluggish or motionless. Both eyes may be affected, and equally or unequally; or one eye may be wholly blind, while the sight of the other is perfect. Similar differences are found in the degree of mobility and dilatation of the pupils. Defective motory power in the muscles of the eyeballs or lids sometimes co-exists. The individual, therefore, gropes about with an uncertain gait, his eyes having a vacant stare, and the lids seldom moving or almost fixed.

Examination with the Ophthalmoscope can alone determine and complete the diagnosis.

*Causes.*—The causes of amaurosis are various, and relate either to the nervous or vascular portions of the optic apparatus, or to both. Thus, over-stimulation and *exhaustion* of the retina, by long-continued exertion of the eye on minute objects, or by exposure to glaring light; *anæmia*; or *determination of blood* to the head, as from any stooping occupation or intemperance; or amaurosis may be consequent on *inflammation* or *degeneration*, the *pressure* of extravasated blood, of tumours, or aneurism: or arise from *injury*, as fracture with depression, or concussion, severally affecting the retina, optic nerve, or brain. Besides these local causes, amaurosis may be symptomatic of irritation in a *distant* organ or part—sympathetic amaurosis—*e.g.*, from disorders of the digestive organs, irritation of the fifth pair of nerves, as by tumours or carious teeth; or it may result from *blood-poisoning*—*e.g.*, by lead, or belladonna.

*Treatment.*—Many morbid conditions of the retina and choroid, or further and unknown states of the optic nerve and brain, being associated together, but which have nothing in common with each other, excepting the symptomatic state known as Amaurosis, or dimness of sight, &c., there can be no special treatment of this visual affection. It must differ according to the particular *cause* of the Amaurosis.

The removal of the cause can be accomplished only by having due

regard to its nature. Any amaurotic occupation may be discontinued, whereas, a structural change will probably be permanent and incurable. Remedial measures—also having reference to the particular condition of amaurosis—pertain chiefly to an atonic state, nervous or vascular, hyperæmia and inflammation, sympathetic irritation, and blood-poisons. The treatment with reference thereto must be conducted on ordinary principles.

THE OPHTHALMOSCOPE. — It is scarcely more than twenty years ago, since Cumming first demonstrated the possibility of inspecting the fundus of the human eye, by means of a certain arrangement of light. An instrument for this purpose, the first ophthalmoscope, was invented by Helmholtz and described in 1851. Ruete followed in 1852, with an ophthalmoscope constructed on a different principle; Coccia modified this instrument, and it was still further modified by Anagnostakis, who reduced its construction to extreme simplicity, and perfected its utility.

This ophthalmoscope consists merely of a circular mirror, about an inch and three-quarters in diameter, slightly concave, and perforated in the centre with a round aperture, the tenth of an inch wide. The mirror is set in a metal frame, fixed in a handle.

The eye of the patient should be prepared for inspection by dilating the pupil with atropine, unless it be already dilated from disease.

The application of the Ophthalmoscope, in regard to the various details necessary for a complete examination of the eye, is thus described by Mr. Dixon:—"The observer and the patient sit face to face, in a room from which daylight has been excluded, the only source of illumination being a lamp, or, still better, a jet of gas issuing from a jointed tube, so that the flame can be placed higher or lower, according to the height of the patient's head. The flame should be on a level with his eye, and just far enough behind him to prevent any of the direct rays falling on his cornea. The chimney surrounding the flame must be of transparent glass, and, if faintly tinged with blue, it will modify the red rays of the flame, and impart a whiteness to it, nearly resembling that of ordinary daylight. The observer places the back of the mirror close to his own eye, so that he looks through the central aperture, and holds the instrument at such an angle that the reflected light from it falls upon the patient's pupil. This is always very difficult for a beginner to accomplish; but a little practice soon makes it easy. The observer will know that he holds the instrument in the right position, and at a proper distance from the eye, by seeing the retina assume a brilliant reddish appearance. Still holding the ophthalmoscope in the same position, he takes in the other hand a convex glass, of two inches or two inches and a half focus, and places it at such a distance in front of the cornea as to allow of the retina coming within that focus. If the fundus of the eye be properly illuminated, and the convex glass correctly placed, some of the retinal vessels will now be distinctly seen.

To bring the optic nerve into view, the *patient* must direct the eye a little towards the nose, and by turning the eye in various directions every portion of the retina is successively brought under the view of the observer. The necessity for varying the position of the eye constitutes a great objection to the more complicated ophthalmoscopes, which are fixed to a table or other support; and some eyes are so unsteady, and so little under the patient's control, that the observer is obliged to follow their

movements by slight changes in the position of the ophthalmoscope, which can only be effected when the instrument is held in the hand.

Some ophthalmoscopes present an upright, some a reversed image of the optic nerve and retina. The simple mirror of Anagnostakis, used in combination with a convex glass, in the manner here described, certainly allows of our seeing, in their real position, parts which do *not* fall within the focus of the patient's crystalline lens."

HEALTHY APPEARANCES.—(1) *Retina*.—The colour of this tissue is not uniform in every eye: its tint varies from pale red through shades of red, orange, and yellow orange, to buff. In a full-blooded person, and with a vigorous state of the circulation, the colour is much redder than in the anæmic, and with a feeble circulation. The colour of the retina is partly due to its own capillary network, and partly to the vascular choroid behind it; the amount of redness thence transmitted depending on the quantity and condition of the hexagonal pigment between it and the retina. The retinal vessels radiate from parent-trunks—the central artery and vein, issuing from a central point in the optic nerve. The arteries present some features of distinction from the veins. An arterial trunk has a more direct course, is of smaller calibre, a paler red colour, and presents a double outline, as compared with the adjacent vein; both these latter peculiarities of appearance depending on the greater thickness of the arterial wall. This distinction becomes less marked as age advances. No pulsation can be detected on simple inspection, but pressure on the globe elicits a distinct pulsation, both in the arteries and veins. The sight, in this state of the circulation, may remain unimpaired.

(2) *Optic nerve* at its ocular extremity—the *Optic disk*.—This structure presents a great variety of appearances, and which do not affect the sight. The optic disk has a circular shape, and its colour, as compared with the reddish tint of the surrounding retina, is creamy white, or sometimes a pinkish-gray as in the cortical portion of the cerebral convolutions. The extreme margin of the disk is more decidedly white than its area. From the centre of the nerve-disk, the retinal artery and vein emerge; commonly, each as a single trunk, sometimes in two or three trunks. The vessels pass off the nerve in straight or wavy lines, or sometimes form several abrupt curves on the surface of the nerve before quitting it. As age advances, the optic disk deviates from the circular form, becomes smaller in size, and of a darker tint, approaching gray.

(3) *Choroid*.—The distinctness of this tissue will depend on the degree of transparency of the retina, and the condition of the hexagonal pigment-cells intervening. The appearance varies also considerably with age. In young persons, the choroidal vessels are dim and indistinct, as if overspread with a thin semi-opaque film; but, in old persons, these vessels appear as if not overlaid by the retina. They are much larger than the radiating retinal vessels, closely packed with narrow linear interspaces, showing dark pigment. The colour of the choroidal vessels changes during life; at an earlier period presenting a bright red, in old age, this colour becomes mixed with a brownish tint.

(4) *Vitreous humour, aqueous humour, the lens, and its capsule, and the cornea*.—These parts of the eye are transparent, in the healthy state, and thus admit of clear inspection of the whole of the posterior portion of the interior of the eyeball. Contrasting with the healthy state, as the standard of comparison, the morbid appearances of the same tissues within this portion of the eyeball have already been described. They remained

for centuries unknown, and they never could have been discovered without the aid of the ophthalmoscope. This instrument has, in fact, revolutionized the pathology of deep-seated diseases of the eyeball, and this department of Ophthalmic Surgery.

**GLAUCOMA.**—An inflammatory condition, apparently, and which gradually involves every tissue of the eyeball; resulting in its complete and permanent disorganization, with total blindness.

**Acute Glaucoma.**—The sight is rapidly lost. The attack commences—usually in the evening—with dull pain in the eyeball, redness of the sclerotic and conjunctiva, and mistiness of sight. The *pain* soon acquires an acute and neuralgic character, piercing through the ophthalmic division of the fifth nerve, and radiating even to the second and third divisions. In a few hours, the iris has acquired a slaty discoloration, and the pupil become irregular in form, dilated and quite immovable. In a day or two the cornea loses its brilliancy, the conjunctival epithelium appearing minutely granular. The eyeball is singularly tense and of *stony-hardness*; and the slightest pressure aggravates the pain. Sight is lost by this time, possibly within a few hours, and so completely that even a bright light cannot be perceived. One eye only may be attacked, but frequently the other eye follows in a variable period; one, two, or several days.

The period of life is usually past middle age; and some break-down of the general health or mental anxiety seems frequently to have predisposed to the attack.

**Chronic Glaucoma.**—The eye has undergone the same structural changes, only in a more confirmed and conspicuous state. Thus, the tension and stony-hardness of the eyeball is greater, and the vascularity of the sclerotic more pronounced; it being marked with faint dusky patches, and sometimes a slight vascular zone, and traversed by large purple tortuous veins emerging abruptly close to the margin of the cornea. *Opacity of the lens* is the distinctive character; this body has also a full swollen appearance, as if it had undergone maceration, and were almost bursting through its capsule; its *colour*, moreover, has changed to a grayish or greenish drab, dirty yellow, or dull orange tint. This greenish or glaucous aspect of the lens, appearing as it were a reflex tint from the fundus of the eye, was formerly regarded as essential and peculiar to the disease, glaucoma.

The order of *sequence* of the morbid changes would seem to be;—congestion in the retina and choroid, continuing perhaps to effusion between these two structures. Hence, pressure on the vitreous humour, and bulging forwards of the lens and iris; followed by congestion and inflammation of the iris and cornea, the lens becoming opaque as a result of its impaired nutrition. Sight is lost, certainly as to the perception of objects, sometimes the retina is even insensible to light.

The disease, in its chronic form, is of insidious origin and slow progress; advancing, with intervals of cessation, during months or years. It occurs in persons beyond middle age, and who have a pale, worn appearance.

The granular condition of the corneal epithelium, the haziness or complete opacity of the cornea, in Glaucoma, precludes any examination of the fundus of the eye by means of the ophthalmoscope. It thus differs from Amaurosis, in respect to the applicability of this exploring instrument. Usually, nothing more can be discerned than a faint reddish glow

from the retina, without any trace of the optic nerve or retinal vessels. It is important to bear in mind this absence of what are sometimes designated, the ophthalmoscopic appearances within the eye in Glaucoma. Probably appearances so described have reference to Amaurosis with excavated optic nerve; a condition which may co-exist with perfect transparency of all the media of the globe.

*Treatment.*—*Acute* Glaucoma may succumb to prompt antiphlogistic measures; cupping, counter-irritation, and constitutional treatment as perhaps that for rheumatism or gout. Opium may relieve the pain. *Chronic* Glaucoma is altogether beyond the reach of any such treatment; the structural disorganization cannot be prevented, it having already taken place, more or less completely.

*Iridectomy.*—This operation was proposed by Graefe, in 1857; and it has proved more successful than any other mode of treatment. It consists in removing a portion, about one-sixth, of the iris, by a small puncturing incision through the cornea close to the sclerotic; the iris being seized with a fine forceps, is drawn out sufficiently, and the portion cut off. Thus, it was said, the “intra-ocular pressure,” on which the whole state of the eye depended, would at once be relieved, and the Glaucoma *cured*. When, however, complete structural disorganization of the eye has taken place; evidently, the operation must be unsuccessful.

**SHORT SIGHT, and LONG SIGHT.**—These conditions represent exclusively the *range*, not the power or clearness, of vision. They depend on alterations, either in the refractive power of the transparent media of the eye, as an optical instrument, or in the adaptive power of the organ; in either way, the focusing power of the eye is altered. And such alteration is of an opposite character in the two ranges of vision.

*Short-sight—Myopia.*—In this state of visual range, the eye can see near objects clearly, while distant ones appear dim and confused. The rays which ought to come to a focus upon the retina, converge to a point in *front* of it. This has been attributed to over-convexity of the cornea, but the convex cornea of a far-seeing bird disproves this explanation. Short-sightedness seems to arise from one or more of three causes; over-convexity of the lens, elongation of the globe in its antero-posterior axis, or from an unusual power of adapting the eye to near objects by changing the position of the lens. The ciliary muscle is probably brought into action in the adaptation of vision, thus increasing the convexity of the lens, and consequently its refractive power.

The habit of looking at minute objects may have this effect, and assuredly induces short-sightedness. Hence certain occupations from childhood upwards, have a causative influence; as in learning to read or the study of music; and certain classes of persons are more subject, as literary men, and artisans engaged in delicate and minute manipulations. Out-door pursuits have rather a preventive tendency. Commencing, usually, a little before puberty, short-sight increases up to about the age of twenty-five; when the focus settles down to that which remains permanent through life. The sight does not improve as age advances. This affection is frequently hereditary.

*Treatment.*—Any habit or occupation inducing short-sight must be abandoned; and an opposite habit or pursuit cultivated. The optical remedy consists in using *concave* glasses, of a focus suitable to the individual case; and worn only as occasion requires. Spectacles—not a single glass—of the lowest concave power sufficient to compensate for the myopic

condition, should be the first selected; and these exchanged for a higher power when felt to be necessary.

*Long-sight—Presbyopia.*—In this state, small and near objects appear indistinct, while distant ones are seen clearly. The rays of light come to a focus *behind* the retina. This condition may be due to flattening of the lens, diminution of the antero-posterior axis of the globe, or from want of the power of adjustment.

Long-sight commences about the turn of life,—say fifty; reading then becoming more and more difficult. The book is held at some distance, even arm's length, from the eyes; and there is as much straining and sense of effort to look at a sufficient distance away from the object,—in order to bring the focus forwards to the retina, as in short-sight to look nearer,—thus to turn the focus backwards to the retina. This difficulty of long-sightedness increases as age advances.

*Treatment.*—Any endeavour to accustom the eyes to the nearer range of former years, should be abandoned, as being foolish and prejudicial. *Convex* spectacles must at once be resorted to; the lowest power which may be required being used first, and increased as the sight demands. The *test* of sufficiency in respect to the glasses selected for short-sight, or for long-sight, is, that the person shall be enabled to see objects distinctly at the average distances of sight, without any magnifying effect or sense of effort.

*Faulty perception of Colours.*—Colour-blindness,—*acritochromacy*, is an inability to discriminate between colours. Various other terms have been devised to designate this defect. It is generally an inability to perceive red, and the compound tints into which this colour enters. Blue is almost always appreciated; and yellow, always. The cause of this defective perception, is probably not in the eye itself, but in that portion of the brain to which the impressions of light are conveyed. It is a cerebral affection, but may be temporary. An important practical suggestion was made by Wilson, that persons employed on railways and elsewhere, who are required to observe coloured lights as signals, should be previously tested as to their power of perceiving colours with perfect accuracy.

No treatment can be said to be curative or even palliative.

*Day-sight* or *Hemeralopia*, and *Night-sight* or *Nyctalopia*; are terms used to designate intermittent blindness, conversely, by night, and by day.

*Day-sight* is perfect in broad daylight, but the power of vision declines after sunset and in twilight. This loss of function is caused apparently by exhaustion of the nervous power of the retina, from exposure to strong sunlight; the weaker stimulus of twilight or moonlight then being insufficient to produce the sensation of light. Hence this deficiency occurs commonly in tropical countries, and in persons who have just returned from long sea-voyages, especially from the East or West Indies.

Rest of the over-stimulated retina would seem to be the most important indication of treatment; coupled with tonics and good food when toil and hardship have contributed to the exhaustion.

*Night-sight*, or inability to see by daylight, is not probably a special affection, independently of any inflammatory or other disease of the eye which may be attended with intolerance of light. Scrofulous ophthalmia is thus nyctalopic.

DISEASES OF THE EYEBALL, or of its MOTOR APPARATUS.—(1) *Protrusion of the Eyeball.*—An unnatural prominence of the eyeball may be

unconnected with any disease of the organ. The eyes have a peculiar and painfully staring expression, as if they were too large for the sockets. The lids can be shut, the eyes moved freely in all directions, and sight is unaffected. Both eyes are equally prominent. These peculiarities distinguish this condition from the projection caused by any orbital tumour.

It exists or occurs mostly in women of feeble or hysterical constitution, and would seem to be due to an atonic state of the recti muscles; but the free movement of the eye is incompatible with this explanation of the protrusion.

No known *treatment* has any remedial influence.

(2) *Dislocation of the Eyeball*—from its socket—cannot take place without rupture of the optic nerve, allowing the eye to be thrust out upon the cheek. Lodgment of the upper eyelid backwards, behind the greatest convexity of the globe, has occasionally happened.

(3) *Tumours within the Eyeball, or Orbit*.—Various kinds of tumour are liable to form in this, as in other parts. *Cancer* is, perhaps, the most frequent; *hydatids*, or *exostosis*, are occasional forms of growth.

The *diagnosis* of an intra-orbital growth will be difficult, and perhaps impossible, at an early period; and still more so, its nature. All give rise to gradual displacement and protrusion of the eyeball. The anterior portion of an intra-orbital growth can sometimes be examined with the tip of the finger between the orbit and globe, in this situation. Hydatid cysts present a feeling of elasticity and fluctuation, and by a fine puncture sometimes, the true nature of the mass is discovered. An intra-ocular growth will probably be shown by the ophthalmoscope. At a subsequent period of growth, the nature of the tumour may be partly determined by its progress. Encephaloid tumour, and the melanotic variety in particular, progresses most rapidly; exostosis, most slowly. When the eye has burst, the kind of tumour may be declared; as, for example, a fungoid melanotic tumour.

*Treatment*.—No medicinal treatment has any more controlling influence over an orbital or ocular tumour, than in respect to the same kind of growth situated elsewhere.

The operation of removing a morbid growth from the orbit implies a previous exact diagnosis, as to whether it involves the eyeball, and is limited to the orbit or extends into it from the cranium. Such diagnosis will mostly be impossible. In performing the operation of extirpation, any injury to the globe or optic nerve must be most carefully avoided; another difficulty, if not impossibility.

REMOVAL OF THE EYEBALL.—(1) *Partial removal*.—Non-malignant disease, and occasionally destruction of the eye, by, or in consequence of injury, are the conditions which may justify excision of the anterior portion only of the eye, with a view to afterwards introducing an artificial eye.

No particular directions are requisite for the performance of this operation. The removal of a staphylomatous projection of the cornea or sclerotic, by means of a cataract-knife, sufficiently illustrates the operative proceeding. The eye collapses, the sclerotic case left shrinks into a nodule, forming the base of support, and when tenderness has ceased, an artificial scale eye is introduced between the lids.

*Extirpation of the eyeball*.—Removal of the whole eye should never be resorted to while any sight remains in the organ; *excepting* for malign-

nant disease, or when the irritability of a partially disorganized eye threatens to affect the sight of the other eye, sympathetically.

The operation is best performed as follows:—The patient reclining, and under the influence of chloroform, an incision is made from the outer commissure of the lids backwards, to a sufficient extent just to gain free access to the globe; the lids are then held well apart by retractors or curved spatulæ in the hands of an assistant. By passing the knife from the incision to the inner commissure, above and below the globe, carefully avoiding any exposed portion of either lid, the conjunctiva is entirely divided, with the ocular attachment of the levator palpebræ and other surrounding muscles. Then, seizing the globe with hooked forceps and drawing it inwards, the knife enters the orbit externally; the eye is detached, the optic nerve and artery are divided at the apex of the orbit, and the attachments severed internally, thus completing the extirpation of the organ. The lachrymal gland should be removed also; it is commonly involved in the disease of the ball, and is always useless, or its presence would occasion inconvenience afterwards, as I have noticed by a continued secretion of tears overflowing the cheek. Hæmorrhage must be arrested by sluicing with cold water, and the application of a graduated compress, well placed upon the artery at the apex of the orbit. The eyelids are closed, and a light bandage drawn round the head covering the other eye.

Opiates will have to be administered from time to time, to relieve the severe penetrating and claspings pain in the head. The compress may be removed in about two days, according to the probability of hæmorrhage, and not reapplied unless it should recur. The orbit is to be gently syringed, the wound cleansed, and water-dressing applied, or other dressing on ordinary principles of treatment.

**STRABISMUS, or SQUINT.**—The pathology and causes of Squint have already been noticed in connexion with Deformities of the Face (p. 596). It remains only to here describe the operation for its cure or relief.

**Operation.**—The old operation of 1840, when first the cure of strabismus by *tenotomy* was introduced, consisted in dividing the tendon of the internal rectus muscle, for convergent strabismus, in the following way:—

The lids being held apart by an assistant, a small, sharp, hook was stuck into the sclerotic, close to the inner margin of the cornea, so as to fix the eyeball and draw it outwards. (Fig. 327.) Then, the Surgeon raising with the forceps a fold of conjunctiva midway between the cornea and plica semilunaris, divided it vertically with scissors, snipped through the subconjunctival tissue covering the tendon of the muscle, passed under it a blunt hook, or director, and upon this divided with scissors, or with some

kind of knife, either the tendon itself or the adjacent muscular portion of the rectus muscle.

The defects of this mode of operation were, a too great separation of the ocular conjunctiva, inducing a subsequent retraction of the semilunar fold, and an over-weakening, amounting sometimes to utter loss of action, of the divided muscle.

FIG. 327.

*Sub-conjunctival* division of the tendon of the contracted muscle is now commonly practised. This operation, as for convergent squint, is thus performed:—"The lids," says Mr. Dixon, "are kept asunder with a spring speculum (Fig. 328); and an assistant draws aside the globe, by nipping up with the forceps a little fold of loose conjunctiva near the margin of the cornea, at the opposite side to that on which the muscle is to be divided. Supposing the internal rectus to be chosen for operation,

FIG. 328.

the Surgeon, with scissors, divides the ocular conjunctiva horizontally, on a level with the lower edge of the cornea, and extends the incision towards the semilunar fold. Then he nips through the sub-conjunctival tissue, and having clearly exposed the sclerotic, slides upwards, between it and the rectus, a curved director. This serves to raise the muscle and make its fibres tense, and then with scissors the muscle is

carefully cut through, close to its insertion into the sclerotic. This section of the muscle cannot be completed at a single stroke, but requires repeated use of the scissors, so that no fibres may be left undivided. A careful exploration with the blunt hook or director must be made, to detect any undivided fibres, before the spring speculum is finally withdrawn."

The advantage of this improved mode of operation is, that it prevents the deformity arising from retraction of the semilunar fold, which presents a most conspicuous sort of cavity at the inner corner of the eye, almost worse, in appearance, than the leering cast of squint. The instruments required are fewer: no sharp hook, nor the multiplicity of curious little knives, formerly used and abused.

*Graefe's* operation consists, in dividing the conjunctiva a little below the equator of the globe and a few lines from the cornea, almost over the insertion of the tendon; then, exposing the sclerotic just enough to pass a curved blunt hook beneath the tendon, which is drawn well into the conjunctival wound before using the scissors. It is then snipped through close to its sclerotic attachment.

The advantage of this method is, that the tendon is brought quite into view, and, therefore, not likely to escape division, which is one of the dangers of the sub-conjunctival operation.

Division of each internal rectus is generally requisite, even when inversion of the better eye is comparatively slight. If the squint be wholly confined to one eye, the single operation will be sufficient.

In dividing the *external* rectus, it should be remembered that the muscle is broader than the internal rectus, and is also inserted farther back from the corneal margin.

Chloroform, in operations for strabismus, is convenient for the purpose of steadying the eye; but it prevents the Surgeon ascertaining whether the muscle has been effectually divided, by requesting the patient to attempt inversion, or eversion, of the eye.

*After-treatment* is very simple. A pad of wet lint may be placed over the eye, and retained by a bandage. In a few hours, when the risk of ecchymosis, "black-eye," has ceased, this dressing may be discontinued;

and the eyes at once brought into use, especially for distant objects. Sometimes, a little, button-shaped clot of blood remains in the sub-conjunctival cellular tissue, forming a little prominent excrescence, attached by a narrow pedicle. This may be snipped through some weeks after the operation.

## CHAPTER XLI.

### INJURIES AND DISEASES OF THE EAR.

**INJURIES.**—*Wounds.*—The external ear is sometimes wounded in injuries of the scalp; the lobule and perhaps the pinna or cartilaginous portion of the ear being cut or torn and partially detached.

No such portion, however apparently destroyed, should be removed. The part should be cleansed of any grit or other foreign body, and neatly replaced with a few points of suture and strips of plaster. I once had a remarkable instance of union of the external ear, under it would have seemed most unfavourable circumstances. (P. p. 765.)

*Foreign Bodies.*—Various substances, as bits of stick or pencil, glass beads, pebbles, or peas, are not unfrequently pushed into the ears of children in play. I once found a pin at the bottom of the external auditory meatus.

Such bodies are removed more or less easily. It is always advisable to see the body before making any attempt; both to be certain of its presence and its shape. If deeply placed, it may be discovered by simply drawing the ear outwards and backwards, and inspecting the passage in a good light; or it may be requisite to introduce an ear-speculum, a small trumpet-shaped tube having a brightly-polished interior. *Pointed* bodies can be readily extracted with forceps; round bodies, more conveniently, by means of an ear-scoop (Fig. 329), turned round the body, which is then hooked out or eased out, according to its size. Sometimes, direct manipulation having failed, or as preferable to that method of removal; injecting the ear with tepid water, thrown in forcibly from a large brass syringe, will succeed in washing out the body by the reflex action of the water from the tympanum.

After a fair trial, if the foreign body still stick fast in the meatus, it should be left there. It may become loosened; and this chance is better than poking instruments forcibly into the ear with the view of extracting it, and even then again failing to remove the body. In the one case, inflammation will probably ensue; in the other, it will be inevitable, and death has been known to result.

**DISEASES.**—**EXTERNAL EAR.**—This external appendage is subject to various affections.

(1) *Displacement* as it were, so that the ears project laterally from the head, giving a very unsightly appearance, that of asses'-ears; which not unfrequently occurs in children. It seems to arise from wearing a cap thrust down upon the ears, bending the pinna downwards and forwards;

FIG. 329.

or it may be a congenital deformity. Correction of this displacement may perhaps be effected, by avoiding its apparent cause and contriving that the ears shall have a backward direction.

(2) *Hypertrophy* is sometimes seen, particularly in idiots. A *Fibroid* tumour of either the cartilaginous portion of the pinna or of its lobule, is not uncommon in negroes; in the latter situation, it is described by Paget as having arisen occasionally, in this country, from the irritation produced by wearing ear-rings. This growth is apt to recur after removing it; but the only treatment is excision. *Cysts*, containing a glairy or a sanguineous fluid are occasionally met with in the pinna; the latter cystic formation occurring especially in the insane, and being known as *hæmatoma auris*. *Steatomatous* and *fatty* tumours in the cartilaginous pinna, and *Nævus* or erectile tumour in its lobule, may also be enumerated among the growths to which these portions of the external ear are subject. *Gouty concretions* or *tophi* are not unfrequently deposited in the external ear of gouty subjects. They are specially described by Dr. Garrod in his well-known work.

(3) *Eczema* may be noticed as a not uncommon affection. *Porriigo* also occurs in connexion with the disease of the scalp. I have seen it continue after the scalp-affection had disappeared, and result in a very troublesome discharge from the meatus. These, or any affections common to other parts of the body, must be treated on general principles, or in conjunction with the disease of which it forms part.

*External Auditory Meatus*.—This passage, leading from the pinna to the tympanum, is liable to various affections, which require an examination of the meatus to determine their diagnosis and treatment.

The *meatus* deviates from a straight direction inwards. At the external orifice, it inclines upwards and forwards, then turns a little backwards, and lastly, dips downwards and forwards to the tympanum. The calibre of the passage is narrowest about the middle; the outer opening is larger in its vertical diameter, but the tympanic end is slightly oval transversely, and it has an oblique direction, thus making the floor of the meatus somewhat longer than its roof. Externally, consisting of a fibro-cartilaginous and moveable tube, internally it is an osseous and fixed tube—in the substance of the temporal bone. Throughout its whole extent, the meatus is lined by a thin cutaneous membrane prolonged from that of the pinna. The character of this membrane varies in different portions of its extent. The external orifice presents fine hairs pointing inwards, and numerous sebaceous follicles; the inner glandular portion is beset with ceruminous glands which secrete the ear-wax, an adhesive substance forming a ring around the tube at this its narrowest part; the innermost or bony portion presents a fine, smooth, dry, pearly white, shining appearance; in a healthy state not being coated with wax. The *membrana tympani*, closing the passage obliquely, is grayish white, dry, and semi-transparent. Within it, is seen the handle of the malleus, directed from above downwards, and slightly forwards. This bone, extending about half down the membrane, divides it into an antero-superior and a postero-inferior portion; the one is flat or slightly concave, the other, in a perfectly healthy condition during life, is convex towards the external aperture. This lower portion has also a more glistening aspect; and when inflamed, it becomes highly vascular, thickened, granular or villous, and secretes a purulent matter.

*Ear-speculum*.—The external portion of the meatus may be brought

into view, by drawing the ear in various directions so as to render the meatus a straight tube; the patient being placed in a good light.

But all the foregoing appearances will be seen more clearly, and the examination of this passage completed, by means of the ear-speculum. This is simply a trumpet-shaped tube, having a bright reflecting interior; and made for convenience in two or three sizes.

(4) *Wax accumulation in the Meatus*.—Dark coloured and hardened little masses of wax form, not unfrequently, in the meatus of young persons; such concretions occasion crackling-noises in the head on opening and shutting the mouth, and are a common cause of deafness. They can be seen on examining the passage with an ear-speculum; and Toynbee's instrument which has a double convex shape is the most serviceable.

*Treatment* consists simply, in softening and washing out the wax from the meatus, by injecting tepid water somewhat forcibly by means of a large-sized brass ear-syringe. A trough fastened by a spring from the other side of the head, is placed below the ear to conduct the water into a basin. No air-bubbles should be thrown in from the syringe, and as the waxy-concretions come out into the basin, fresh tepid water should be used. Softening the wax by previously introducing a drop or two of glycerine into the ear, may facilitate its removal. The small elastic suction-bottle and tube, known as Margett's, will enable the patient to pass a gentle stream of warm water into his own ear, as a fomentation. In case of pain or inflammation, this affords great relief.

(5) *Thickening of the cuticle*.—In this state, the cuticle lining the meatus becomes thickened and hardened, assuming a dull white appearance, narrowing the passage, and occasioning some degree of deafness. It may be a consequence of long-continued otorrhœal discharge.

Syringing the ear to remove any loose flakes of cuticle, previously softened if needs be, by glycerine; must be followed by some gently stimulating application. A weak solution of nitrate of silver, or dilute citrine ointment, may be brushed over the membrane; and often with much advantage in restoring it to a thin and healthy state.

(6) *Polypus*.—Three species of polypoid growth may form in the meatus. Commonly, it is a *gelatinous* polypus, the size of a pea or bean, smaller, or larger and even projecting from the meatus; when small, of a florid-red colour, and growing chiefly from the bottom of the meatus. It consists—as shown by Mr. Harvey—of fibro-cellular tissue and fibro-plastic cells, like the structure of gelatinous nasal polypus; and is always attended with discharge. It is a consequence of otorrhœa. Very rarely, a *fleshy* pedunculated polypus forms, nearly colourless, having a thin cuticular covering, and growing usually from the middle glandular portion of the meatus. This species is not accompanied with discharge; it is unattended with pain, and does not appear as the result of inflammation. A third species, is *cancer-tumour*, within the meatus. In its earliest stage, this may not be distinguishable, otherwise than by examination under the microscope after removal; the rapid return of the growth, paralysis of the face, and other signs of the invasion of neighbouring organs, will, eventually, discover the true nature of this kind of polypus.

*Treatment*.—Complete removal of the polypus is the only cure; the point whence it sprung should then be touched with nitrate of silver—repeated from time to time, whenever it threatens to sprout again; and the meatus regularly syringed with an astringent lotion. The lunar caustic should be cast in a very fine stick, like the lead of a patent pencil;

or the blunt end of a fine probe may be coated with it, so that it shall be applied exactly to the right spot. Removal may be accomplished by a twist off with Assalini's hook-forceps; or if more firmly attached, the polypus may be cut off with a fine pair of scissors, or its neck caught and cut through by Wilde's snare. Another ingenious instrument was contrived by the late Mr. Avery for grasping the neck of the polypus.

(7) *Otorrhœa*.—This is a discharge from the external auditory passage, of a purulent or muco-purulent character, thin or thickish, a yellowish colour, and offensive odour. It occurs usually in scrofulous subjects; and the discharge may proceed, either from the mucous membrane lining the passage as a result of catarrhal inflammation, or it may be connected with caries of the petrous portion of the temporal bone, associated with disease and destruction of the tympanum and of the internal ear, as a consequence of otitis.

The *catarrhal* inflammatory form of *otorrhœa* is not uncommon in children, and is apparently excited by cold or stomach disorder, especially during teething. It may accompany scrofulous ophthalmia, porrigo, and other eruptions, or be a sequel of an eruptive fever, or of any weakening illness. The child is feverish and complains of *ear-ache*, the meatus is swollen and vascular, and soon there issues the characteristic yellowish discharge.

*Otorrhœa* may subside as the health improves; or once established, it may continue for years or for life. In the latter condition, or *chronic* protracted *otorrhœa*, the daily discharge acquires an almost periodic character; it is perhaps preceded by itching in the meatus, and relieved by scratching with the head of a pin or other pointed body, which is almost immediately followed by a flow of the offensive secretion. Chronic *otorrhœa* may remit a little occasionally, but this subsidence soon produces a sense of fulness and discomfort in the ear, until discharge recurs, of a thicker curdy consistence and more fœtid odour. It may then be discovered by a stranger on entering the room, or even by the accustomed but unhappy sufferer in an atmosphere of his own creation. Confirmed *otorrhœa* cannot, however, be safely suppressed. The entrance to the meatus becomes enlarged and open, owing to the patient's habitual introduction of a handkerchief on the point of the finger; and the result of the disease is absolute deafness with the affected ear.

*Treatment*.—Catarrhal inflammatory *otorrhœa* in scrofulous children, will probably yield under the application of a large poultice to the ear, followed by astringent injections, if the discharge prove obstinate. There is no occasion for the fear of "driving it in upon the brain," as some mothers imagine. Purgatives and tonics will be required to restore the general health. *Otorrhœa* following internal otitis may be amenable to the same plan of treatment. Astringent injections are even more appropriate, when very gently applied. Twice a day, the ear having been lightly syringed out with warm water to remove the discharge; a tepid lotion of alum, sulphate of zinc, or acetate of lead, should be dropped into the meatus, and after remaining there two or three minutes, be allowed to run out. The general health must be promoted by tonics, alteratives, and aperients, and by warm baths.

Certain contingent states of the discharge require some modification of the local applications. For a very fœtid discharge, a lotion may be used, composed of two drachms of solution of chloride of lime to half a pint of water. If the discharge produces excoriation of the ear or the

neck, these parts should first be fomented, and then smeared with an ointment of hyd. præcip. alb. But it is not advisable, in general, to insert ointments into the meatus. If the discharge be obstinate, the whole interior of the meatus should be pencilled with a solution of nitrate of silver—gr. v. ad ʒj, twice a week, with a camel's-hair brush.

If in the course of the treatment, an attack of acute pain and fever occur, and the discharge stop suddenly, leeches, fomentations, and purgatives must be resorted to; and astringent applications resumed only when the acute inflammatory state has ceased.

*Fungous granulations.*—This condition is a very common consequence of otorrhœa. The granulations are usually found at the bottom of the meatus, or springing from the membrana tympani, or from the cavity of the tympanum, after the membrane has been perforated by ulceration. Sometimes, the membrane is covered with florid granulations, and resembles the *granular conjunctiva*.

*Treatment.*—The solution of nitrate of silver should be regularly applied to the fungous surface by a camel's-hair brush, and astringent injections.

**INTERNAL EAR.**—(1) *Otitis.*—Inflammation of the internal ear or tympanic cavity, may be either acute or chronic.

*Acute otitis* is characterized by pain, most excruciating, generally worse at night, and increased by speaking, swallowing, sneezing, or coughing. Great tenderness around the ear and a feeling of distension of the aural cavity, soon supervene, with throbbing noises in the head and deafness, or rarely, morbid sensibility to sound. The meatus is found more or less red, swollen, and dry; and the membrana tympani dull, opaque, and vascular. Violent fever frequently accompanies these local symptoms. Ulceration of the membrana tympani may take place, and a purulent discharge from the meatus affords great relief or terminates the inflammation. Suppuration within the tympanum and mastoid cells of the temporal bone, occasionally takes place; resulting either in obstinately chronic otorrhœa, caries of the bone, irritation of the membranæ of the brain, abscess in the substance of the brain, or even pyæmia.

*Chronic Otitis.*—The inflammation is frequently insidious, attracting little attention, until it has lasted for a long time. Pain, of a rather trifling character and short duration occurs at intervals, noises in the head, and a gradually increasing dulness of hearing, which is often the first symptom complained of. The membrana tympani has a thickened appearance, and is occasionally covered with cheesy tuberculous matter, or fibrous concretions. Fibrous bands stretch across the tympanic cavity; connecting the inner surface of the membrane to the inner wall of the cavity, or to the incus and stapes; or extending from the crura of the stapes to the adjoining wall of the cavity, enveloping this bone with bands of adhesion. Sometimes, they occupy and block up the whole cavity. Ultimately, the membrana tympani becomes ulcerated, the little bones,—ossicula, are detached and discharged, and the entire middle ear is disorganized. Caries within the mastoid cells and suppuration in the tympanum, may follow.

*Causes.*—Exposure to cold, especially currents of cold air, or sea-bathing; rheumatism or gout, the scrofulous diathesis, or perchance, syphilis; not unfrequently also, otitis is a consequence of an eruptive fever, particularly scarlatina; and occasionally, of some violence, as by forcible syringing or freely probing the ear.

*Treatment.*—Acute inflammation of the tympanic cavity requires prompt and decided antiphlogistic measures. Locally, leeches behind the

ear and the continuous application of poultices or warm fomentations. should be followed by blistering. In the event of any swelling or fluctuation over the mastoid process; Wilde and Harvey both recommend an incision down to the bone, about an inch behind, and parallel to, the attachment of the ear. The intense pain may be relieved by painting with the strong tincture of aconite behind the ear. The general treatment will consist of the ordinary measures for inflammatory fever; having recourse to mercury as a probable means of preventing effusion and its damaging results in the delicate structure of the tympanum. Other, and more specific treatment will be appropriate, according to the constitutional character of the inflammation. Hence, in rheumatic otitis, colchicum and alkaline remedies should be resorted to.

*Chronic* inflammation requires more particular attention to the state of the general health. An apparently scrofulous character of the disease, may be overcome by a course of cod-liver oil, iron, and quinine; a rheumatic character, by iodide of potassium, or guaiacum, combined with tonics; a syphilitic taint, by similar treatment. Local measures—of comparatively subordinate importance—will, however, be rendered more necessary in any accession of inflammation; which must be combated by topical depletion and counter-irritation. Otorrhœal discharge should be washed out of the meatus by gently syringing with warm water: and applications made to the membrana tympani, according to its morbid condition. A thickened, opaque, appearance may be remedied by a mild stimulant solution of nitrate of silver,—two to four grains to an ounce of distilled water, or the dilute citrine ointment; applied once or twice a week, with a camel's-hair pencil. A dry tense state of the membrane, owing to the absence of wax, is in itself a source of great discomfort to the patient; this state may be much relieved by a little glycerine dropped into the meatus at bed-time; a substitute for the ceruminous secretion which was originally suggested by Mr. T. Wakley.

The consequences of otitis severally merit some special consideration.

*Caries* or *necrosis* of the mastoid or petrous portions of the temporal bone, is connected with suppuration within the mastoid cells or the tympanum. Persistent otorrhœal discharge of a fœtid character, abscess perhaps over the mastoid process or among the muscles of the neck, fungous granulations choking the meatus, and dead bone felt with the probe, constitute the more peculiar symptoms; deafness, and probably facial paralysis on the side affected, accompany the destruction of the internal ear.

Little can be done in this extremity beyond removing the dead portions of bone. Sir Philip Crampton drew from the meatus of a young lady a piece of bone comprising the entire internal ear,—vestibule, cochlea and semicircular canals, with a small bit of the inner wall of the tympanum. Urgent symptoms of inflammation of the brain with hemiplegia supervened, but she ultimately recovered with total deafness in the ear. Fœtid discharge must be washed away and corrected by appropriate injections.

*Inflammation of the dura mater*, with effusion of greenish yellow fibrine on, or abscess in, the brain, must be treated according to the directions already given in connexion with fracture of the skull.

*Perforation of the membrana tympani*—may be a consequence of otitis; or of violence, directly or indirectly applied; as by forcibly syringing or poking instruments into the meatus, the accidental introduction of foreign bodies, by loud noises, as the discharge of cannon, by descent in the diving-bell, by violent blowing of the nose and thereby forcing a current of air

through the Eustachian tube, and, by blows or boxes on the ear, or fracture of the petrous bone.

The *symptoms* are, a sense of shock in the ear as if something had given way, bleeding from the meatus, and immediate deafness, more or less complete, according to the size of the aperture. During the act of swallowing, the patient may be conscious of air escaping through the meatus, or he tastes in his throat, substances applied within this passage. Examination with the ear-speculum shows the aperture in the membrane, throwing a shadow perhaps on the tympanum beyond; and if the patient inflate the tympanum through the Eustachian tube, air-bubbles and mucus issue from it.

*Treatment.*—Any inflammatory symptoms consequent on perforation or rupture of the membrana tympani must be subdued, as by the treatment of otitis. Perforation may sometimes itself be closed, by lightly touching the membrane with a blunt probe coated with nitrate of silver.

*Artificial membrana tympani* is a very simple contrivance, for the closure of an aperture indisposed to heal, or of large size; and thus restoring the tympanum and power of hearing. It had long been known that a drop of water or oil put into the ear, enabled a patient to hear, whose tympanic membrane was ruptured; a thin film of the fluid closing up the aperture. Mr. Yearsley, therefore, proposed in 1848, a simple but effectual substitute for the lost membrane—a small piece of cotton-wool moistened with oil or glycerine, introduced through the meatus and applied, by means of a fine probe, against the orifice. Patients can easily be taught to do this for themselves. The cotton is renewed once or twice daily, as occasion requires. Instead of cotton-wool, Mr. Toynbee used another kind of artificial membrane, in the shape of an oval piece of thin India-rubber.

*Collapse of the Membrana Tympani.*—A depression of the membrane inwards, presenting the handle of the malleus unnaturally prominent. Usually a consequence of chronic otitis, the membrane is thickened and opaque; but sometimes it retains its natural appearance. In the latter condition it is said that the patient can hear better during a noise, or when stimulated by a few drops of nitric ether dropped into the meatus. Any contrivance for drawing the membrane outwards seems hopeless.

*EUSTACHIAN TUBES.*—*Throat Deafness.*—The Eustachian tube connecting the cavity of the tympanum and the throat, allows air to enter and escape from that cavity, when necessary. The tubes are not constantly open, but only during the act of swallowing. In this act, Mr. Toynbee showed that the levator and tensor palati muscles open the guttural orifice of the tube, thus affording free egress to the mucus from the living membrane of the tympanum, and allowing air to enter or leave the tympanic cavity.

Inflammation and thickening of the lining membrane of the Eustachian tube, precludes this communication between the tympanum and throat. Hence, ringing and crackling noises in the ear during swallowing or blowing the nose, from the bursting of mucous bubbles. Similar sounds may be heard by the Surgeon through the *otoscope*.

This instrument, as improved by Mr. Harvey, is a flexible stethoscope; one end of which, expanded into a hollow ball, is put over the patient's ear, while the other end is applied to the Surgeon's. Then, if the patient close his nose and mouth, and make the effort to swallow or blow the nose, the tympanum should become inflated; when, therefore

the Eustachian tube is pervious, the Surgeon will hear the impulse of air against the *membrana tympani*; but if the tube contains mucus, he will hear a gurgling or some other noise, and if it be impervious, no sound will be elicited. This experiment should be tried more than once, in evidence of the state of the tube. Swollen tonsils, and a generally relaxed state of the mucous membrane of the fauces and nose, accompany throat-deafness. It arises usually from cold.

*Treatment.*—Astringent gargles, and blistering behind the ears, must be reinforced by a course of iron, quinine, and a generally tonic plan of treatment. The state of the digestive organs should not be overlooked. Mild mercurials, as the *hyd. c. cretâ*, or combined with sudorifics, as in Dover's powder, will sometimes prove singularly efficacious in clearing off an obstinately congested condition of the mucous membrane, with a vitiated secretion. *Removal of the tonsils* and uvula, has been considered curative. But enlargement of the tonsils is not the cause of throat-deafness, and their free removal may seriously affect the voice, the general health, and perhaps the development of the generative organs. Excision of the superficial portion of these bodies may be advisable to facilitate swallowing. *Catheterism* of the Eustachian tube has been proposed with a view of effecting dilatation. Much diversity of opinion might be mentioned respecting this operation; but the balance of evidence is adverse to its efficacy. If deemed advisable, it can be accomplished by introducing a probe, slightly bent at its distal end, along the floor of the nostril, with its point downwards; on the instrument reaching the end of the nasal fossa—the posterior margin of the hard palate, which may be known by its point suddenly dipping down, it should be directed outwards and backwards, when it will readily enter the pharyngeal orifice of the tube. In continuing the probe onwards through the tube, the operation is not altogether without peril; whether in relation to the slender, bony, partition between the tube and carotid canal, or that of the tympanic cavity and cranium, or to the jugular fossa. *Perforation* of the *membrana tympani* has also been proposed as another mode of cure; thus allowing access of air to the tympanum, when the natural communication through the Eustachian tube is impervious. This operation is as little favourable as catheterism, though less hazardous.

**EAR-ACHE.**—**OTALGIA**—Properly speaking, a neuralgic pain of the ear, is distinguished from the ear-ache of otitis by its sudden intensity and paroxysmal character. The causes are those of neuralgia; though, perhaps, the affection may be referable to some local source of irritation, especially carious teeth.

The *treatment* consists in purgatives and quinine, and removal of any carious teeth. Relief is sometimes afforded by the application of tincture of aconite behind the ear.

**DEAFNESS.**—This functional defect has already been noticed as a symptom of inflammatory and other diseases, in various parts of the auditory apparatus. Functional disorder of the auditory nerve is also an imputed cause of the loss of the sense of hearing. Mr. Toynbee, however, has shown that such supposed nervous deafness, even in old people, usually depends on some chronic form of inflammation of the lining membrane of the tympanum. Organic changes in the auditory portion of the brain itself, possibly, complete the parallel between nervous deafness and amaurosis.

*Treatment* in both diseases has a very restricted remedial influence.

## CHAPTER XLII.

## INJURIES AND DISEASES OF THE NOSE.

INJURIES.—(1) *Foreign Bodies* are sometimes thrust into the nostrils of children in play. Pearl buttons, pebbles, peas, or other small bodies, may thus be lodged a little way within the nares, and easily seen or discovered by slightly dilating the nostril with a nasal speculum. (Fig. 330.) Extraction can generally be accomplished by an ear-scoop, or a bent probe, or with the polypus forceps. Failing to remove the body through the nostril, it must be pushed back into the throat.

FIG. 330.

(2) *Epistaxis*, or bleeding from the nose, may in common with other hæmorrhages, be the effect of injury, or induced by some state of the circulation, or of the blood itself; determination of blood to the head in a plethoric subject producing *active* hæmorrhage of arterial blood; disease of the heart opposing the return of venous blood, or the altered state of the blood in scurvy, purpura, and other diseases, producing *passive* hæmorrhage.

In young persons, epistaxis is rarely a formidable hæmorrhage, though I have seen such severe recurring bleeding from fracture of the nasal bones—a broken nose, in a powerful policeman, as well-nigh proved fatal. In elderly and enfeebled persons, epistaxis is often perilous.

*Treatment*.—Slight epistaxis, in young and healthy subjects, may be arrested, when necessary, by sluicing the nose and forehead with cold water, or by cold applied to the nape of the neck; and any tendency to its return prevented by purgatives and emmenagogues. In plethoric persons, to whom epistaxis often acts as a safety-valve, the bleeding should not be indiscriminately checked. Cold, rest, and dry-cupping from the back of the neck, sometimes, however, become requisite, these measures being reinforced by saline purgatives. *Passive* hæmorrhage is best controlled by styptics, administered internally and applied within the nostrils. Gallic acid, in five or ten grain doses, is perhaps the most efficient; and the anterior nares may be plugged with a compress of lint or sponge soaked in a solution of alum, perchloride of iron, or tannin. Any concurrent disease, as the cause of hæmorrhage, must of course be treated. A scorbutic condition often yields to the administration of oil of turpentine.

Severe or persistent epistaxis, or as arising from injury, can sometimes be arrested by elevating the arm to a vertical position on the side corresponding to the hæmorrhage; or both arms when the bleeding is from both nostrils. Malgaigne, in his work on Fractures, mentions a remarkable case of copious epistaxis produced by fracture of the nose in the person of a young man who had been thrown down with his face to the ground. Cold lotions having failed to check the hæmorrhage, he was directed to raise his arm perpendicularly; it ceased immediately, and did not recur.

But severe or persistent epistaxis will generally require the simple operative procedure of plugging the posterior nares, as well as the anterior.

*Plugging the Nares.*—This is most readily accomplished by passing an elastic catheter, armed with a long piece of strong whipcord fastened to its eye end, along the floor of the nasal fossa, through the posterior nares into the pharynx (Fig. 331); then seizing the cord with forceps as

FIG. 331.

it appears behind the soft palate, it is drawn forwards through the mouth, while the catheter is withdrawn from the nostril. The cord, thus passing round the back of the soft palate, hangs out of the mouth and nose. An oblong plug of lint or compressed sponge of sufficient size to

FIG. 332.

occupy the posterior nares, is firmly tied to the cord as it hangs from the mouth, and by pulling the cord through the nose, the plug is drawn back into the posterior nares. (Fig. 332.) The anterior nares is then plugged with compresses of lint or sponge. When, on removing these compresses,

the bleeding has ceased, the posterior plug can be easily withdrawn by the end of cord which hangs from the mouth. Or the plug may be renewed—a fresh, clean, pledget—by means of the nasal end of the cord. Bellocq's sound has been used for introducing the cord, but this instrument may not be at hand; an elastic catheter is surely ready.

DISEASES.—(1) *Hypertrophy* or *Lipoma*.—An overgrowth of the cellular texture and skin of the nose sometimes occurs; presenting a large reddish-blue, lobulated, pedunculated, mass at the end of the nose, arising apparently from enlargement of the sebaceous follicles. (Fig. 333.)

FIG. 333.

This inconvenient and unsightly mass is of slow growth and not dangerous; but the monstrous deformity will compel the unhappy individual to seek relief. It occurs seldom before fifty years of age, and in a somewhat broken constitutional state of health.

Removal with the knife is the only remedy, and a tolerably easy one. An incision is made in the middle line of the nose, and the mass carefully dissected off the alar cartilages on either side, an assistant introducing his finger into the nostril to support the cartilage. The wound usually heals by granulation.

(2) *Cancer*, occasionally, affects the nose, in the form of scirrhus or encephaloid; but more often as epithelial cancer. These forms of growth present the same appearances as elsewhere. Treatment must be conducted in accordance with general principles.

(3) *Lupus*, or *noli me tangere*, seems to have a special affinity for the nose; it is an insidious and obstinate ulceration of the skin, and which produces frightful havoc, by the destruction of one or both alæ, the columna, or the whole of the organ. The diagnostic characters of *Lupus* and *Cancer*-ulcers are described in connexion with these diseases. If the disease be arrested and cicatrization ensues; the remnant nose then

appears truncated obliquely from above the nostrils, exhibiting two dark cavernous apertures with a thin-skinned reddish shining cicatrix—a hideous spectacle. The disease occurs mostly in fair delicate persons, during childhood or adolescence; and in both sexes indiscriminately. It seems to arise from, and be symptomatic of, some constitutional disorder of assimilation and nutrition.

The *treatment* medicinally and hygienic requires no special notice; restoration of the lost portion of the organ—by rhinoplastic operation, forms part of the PLASTIC-SURGERY OF THE FACE.

(4) *Syphilitic Ulcer* of the nose differs from the lupoid and cancerous forms of ulcer. It usually attacks the ala or the tip of the nose, and commences as a small pimple, red, hard, and somewhat painful, which suppurates and opens into an ulcer. Sometimes, the skin over the fibro-cartilages inflames and gives way, by a crack or fissure. Thus far there is nothing characteristic. But, the resulting ulcer has an irregular, fringed margin. The discharge is ichorous and encrusting; the ulcer, at the same time, eating away beneath. A faint blush surrounds the ulcer. These appearances must, however, be taken in connexion with other present or past manifestations of constitutional syphilis, to complete the diagnosis.

The *treatment* is that of secondary syphilis. Mr. Ure found iodide of potassium—when mercury had been previously given—most efficacious, in conjunction with a lotion of bichloride of mercury, a grain and a half to the ounce of water. Under this treatment, an ulcerated patch soon healed, which had extended from the ala to the tip of the nose, and which was of fifteen months' standing.

NASAL FOSSÆ.—(1) *Ozæna* or *Rhinorrhœa*.—A muco-purulent or sanious discharge, having a fœtid odour, yellowish or greenish colour, and coming from one or both nostrils. Proceeding from the mucous membrane lining the nasal fossæ—here named pituitary or Schneiderian membrane, this discharge is symptomatic of various ulcerations of that membrane, involving perhaps the bones forming the fossa. Thus may be recognised *Catarrhal Ozæna*, which sometimes accompanies chronic catarrh; *Scrofulous ozæna*; and *Syphilitic ozæna*. The diagnosis must be mainly determined by the concomitant and antecedent constitutional condition. Impaction of a foreign body in the nasal fossa will at length give rise to an ulcerative discharge. Injury to the nose is occasionally followed by *ozæna*. One of the worst cases of *ozæna* I ever saw; was the result of contusion of the bridge of the nose; apparently without any syphilitic taint or other constitutionally predisposing cause. The nose often has a broad and flattened appearance—the nez écrasé of French authors.

*Ozæna* commences in infancy or in adolescence, and in either case frequently lasts through life. It has been known to subside when menstruation is established, or after childbirth. But it is rarely cured, excepting at its outset, and that in young subjects.

*Treatment*.—Various stimulant and astringent applications may be used with advantage to modify the vitality of the pituitary membrane; such as very dilute solutions of nitrate of silver, sulphate of copper, and chloride of zinc. Professor Gross recommends an injection of three grains of tannin with a quarter of a grain of sulphate of copper to an ounce of distilled water. Deodorizing injections must be used to correct the stench; such are chlorinated solutions, and dilute solutions of creosote,

carbolic acid, or permanganate of potash. Trousseau extols the insufflation of calomel, conjoined with an injection of bichloride of mercury. In Ozæna which has persisted for a period of years, and is attended with superficial erosion of the mucous membrane; Mr. Ure has prescribed with advantage a liniment of fifteen grains of chloride of zinc and one ounce of olive oil; which is to be pencilled over the affected part, once a day. A peculiar caustic-holder has been devised by Cazenove for applying nitrate of silver in ozæna.

*Abscess, ulceration, caries and necrosis*, in the nasal fossæ, are all intimately connected with ozæna, and scarcely require a separate notice.

*Abscess* forms most frequently on the septum nasi; and is often associated with a scrofulous taint in the constitution; the presence of an exanthematous fever, as small-pox, measles, scarlatina; or with injury of the integument—a wound situated near the lower end of the nasal bones. The integument becomes œdematous and tender, the pituitary membrane inflamed throughout, and the portion covering the septum is uniformly turgid. Matter forms, and a prominent, red, shining, and fluctuating swelling—in one or both nostrils, obstructing the passage. Pain extends up the nose to the frontal sinuses, and the swelling enlarges downwards, protruding the upper lip. Abscess in both nostrils usually communicates through the septum. The *treatment* is simply that of any other abscess. An early incision, and so as to give free vent to the pus, affords great relief. The opening must be maintained, lest the matter reaccumulate. The discharge, at first sero-purulent, assumes a glairy consistence.

Chronic abscess of the septum is very insidious. Destruction of the bones, cartilages, or both, not uncommonly results, and even after apparent cure of the abscess.

*Ulcer* occurs in any part of the nasal fossa, but mostly at the angle of the ala and septum, or between the ala and tip. Any such ulcer is very painful and chronic. The *treatment* consists in the application of white precipitate ointment, an excellent remedy; or perhaps citrine ointment or nitrate of silver. General remedial measures must have regard to the constitutional condition.

*Caries and necrosis* may also affect any of the bones forming the nasal fossæ; but here again, the septum, more especially. The nasal bones participating, a marked flattening of the nose ensues, as the bridge sinks in the course of destruction. Such may be the result of syphilitic ozæna. The only special *treatment*, is the removal of the dead portions of bone with polypus-forceps.

(2) *Thickening of the Schneiderian Membrane*.—This state of the nasal mucous membrane not uncommonly occurs throughout the whole extent of the fossa, and in both nostrils; frequently the thickening or hypertrophy is limited to the portion of mucous membrane underneath the inferior spongy bone. But here the membrane is naturally thick, as Kölliker points out, owing to its glandular character and abundant, almost cavernous, venous plexuses.

*Symptoms*.—The affection causes uneasy breathing, especially during cold and damp weather; there is also perceptible swelling in the nostril, resembling polypus; but, it is of a deeper red colour—never grayish, and not pedunculated. It may also, unlike polypus, be situated on the septum nasi. These appearances were well-marked in a case which came under my notice many years ago; and in that instance the lower part of the

nose was bent to the side opposite to the thickening, thus exposing its characters more clearly.

Thickening of the membrane, as thus described, may arise spontaneously, or follow *chronic coryza*. This latter is an inflammatory affection of the Schneiderian membrane, in a chronic state, and distinguished by a thin, acrid, ichorous discharge from the nostrils. It may be catarrhal, or have a syphilitic or scrofulous constitutional origin.

*Treatment*.—The topical application of astringents, by means of the injections already noticed with reference to *ozæna*, will probably reduce chronic thickening of the membrane and restrain any coryzal discharge. But these measures must be supported by appropriate constitutional treatment, as also requisite in the various forms of *ozæna*.

(3) *Polypus*.—Tumours of very different kinds growing within the nostrils, are associated under the common term, nasal polypi. They agree only in being pedunculated, and as obstructing, more or less completely, the nasal passages. Their structural differences, and distinctive characters are as follow.

*Gelatinous* or *Mucous* polypus—the ordinary form of growth. This is a soft, pulpy, slightly elastic tumour, of a grayish brown colour, somewhat translucent, and lobulated, attached by a peduncle to the mucous membrane. It consists of the elements of this membrane, a fibro-cellular

FIG. 334.

texture covered with ciliated epithelium; it is slightly vascular, and more so at the root of the tumour. It is attached, commonly, to the middle spongy bone or middle meatus, extending perhaps an inch from before backwards (Fig. 334); sometimes growing from the other turbinate and ethmoid bones; occasionally from the roof of the nares, or even from the frontal sinuses or antrum; never from the septum. More than one polypus usually forms at the same time; and, several co-existing, each has a distinct peduncular attachment. But the lowest or

most anterior readily presents downwards in the open nostril, while the others are concealed and compressed; one overlaying another or others, like toadstools in their growth. Polypi may form in both nares simultaneously.

The growth increases in size rather slowly and gradually, restricted, probably, by the osseous boundaries of the nares. Occupying, and more or less completely blocking-up the passage, the tumour may come forwards to and through the nostril, or extend backwards over the soft palate to the fauces, and hang down into the pharynx. The bones and cartilages seldom become diseased, but displaced; thus enlarging the nasal fossa, and resulting in considerable expansion of the nose. Having a succulent character, owing to its cellular structure, this species of polypus is hygro-metric; diminishing in dry, warm, weather, and increasing and becoming plump, or even protruding, in moist weather. It may occur at any period of life, but is most common in adults.

The *symptoms* are, a sense of stuffing in the nostril, as if proceeding from a constant cold in the head, and which varies with the state of the

weather. A thin mucous discharge from the nose, and fits of sneezing, complete the illusion. Respiration through the nares becomes embarrassed more and more, the patient breathing with his mouth open, and sleeping thus with his head thrown back, snoring loudly. The voice acquires a nasal twang, is indistinct and snuffling; and the special senses, connected with surrounding organs, become affected by the polypoid growth. Smell and taste are impaired or lost. Deafness ensues, due, as Mr. Toynbee states, to a co-existent thickening of the membrana tympani. In addition to symptoms, certain *phenomena* may be elicited. On stopping the free or partially-free nostril, by pressing that side of the nose with the finger, the patient cannot breathe through the affected nostril, or imperfectly, the air being expressed by a forcible effort, with a whizzing or singing sound. The patient then feels something shifting its place to and fro in the nasal cavity, and the Surgeon hears a peculiar noise, like, as Dupuytren compared it, to the flapping of a flag. Sometimes the polypus thus descends into sight. On directing the patient's head backwards, the polypus will be seen, or brought into view by dilating the nostril a little with a bivalve nasal speculum; and the tumour is observed to have the characteristic appearances already mentioned. Ultimately, the nose acquires a peculiar broad, laterally dilated, or *frog-faced* aspect; giving a singularly heavy, stupid, expression to the upper part of the face. (Fig. 335.)

FIG. 335.

*Diagnosis.*—Gelatinous polypus must be distinguished from common catarrhal coryza, from thickening of the mucous membrane covering the middle spongy bone, from displacement of the septum to one side, from abscess of the septum, and from an extraneous body, as a fruit-stone or a nasal calculus. Certain other polypoid growths are also liable to form in the nasal fossa, but these may be diagnosed chiefly by their special characters.

*Fibrous polypus* presents a firm resistant tumour, instead of a soft, elastic, substance like an oyster; and which does not vary in size with hygrometric changes. It is more broadly pedunculated, and springs from the periosteum beneath the mucous membrane. Its structure is essentially fibrous, and much more vascular than gelatinous polypus. Sometimes, according to H. Cloquet, it becomes encrusted with phosphate of lime, and partially ossified. It may spring from the septum, and is usually solitary.

This species of polypus grows more rapidly, attains a larger size, and, owing to its higher vascularity, has a greater tendency to bleed. Increasing in size, the tumour causes greater displacement of the surrounding bones in the nasal fossa—as deviation of the septum, depression of the palate, projection of the nasal bones; or it extends backwards and is prolonged into the pharynx. It is also apt to send offsets into the various sinuses, in the frontal, ethmoid, and superior maxillary bones, thus appearing in situations where little expected, as in the pterygo-maxillary fossa, or in the orbit through an aperture formed in its inner wall.

All the *symptoms* due to the presence of a tumour in the nasal fossa, are much more aggravated.

*Malignant or Cancerous Polypus*.—This, the third species of polypoid growth, is a soft tumour, of a deep red or dark purple colour, prone to bleed, and painful; fixed to the bone, and springing, perhaps, from a greater depth, within the cranial or sphenoidal cells. The nasal portion may be only the external protrusion of a deep-seated medullary tumour. Growing rapidly, with great expansion of the nostril, it tends to protrude through the nasal or lachrymal bones, and frequently displaces the eye. It discharges a fœtid, bloody, ichorous fluid; while repeated hæmorrhage, and acute, lancinating pains, striking up into the root of the nose and forehead, accompany the development of this species of polypus, and reduce the patient's strength to the last extremity. The disease occurs only in adults or in advanced life.

TREATMENT.—The three species of polypus, above described and contrasted, are incurable by any known medicinal treatment, whether local or constitutional. Removal by operation is the only resource, but the different species of tumour are thus removable with very different degrees of facility, and probability of non-recurrence.

*Gelatinous* polypus, very rarely, may separate, and is expelled *spontaneously*; and its ejection has been known to happen, after the repeated application of strong stimulant injections, by sloughing of the tumour. But this would be an uncertain and incomplete result, and probably followed by recurrence of the growth.

This species of polypus is, usually, extracted with *forceps*, by a combined movement of pulling and twisting. Forceps having rather long, serrated blades, to hold securely—nasal polypus-forceps, are used for the extraction, the instrument being made of sufficient length, slender, and straight, or slightly curved, according to the situation of the polypus. The neck of the polypus is first clearly ascertained by running a probe round the tumour, above and below the middle spongy bone, or its peduncular attachment elsewhere. Then—the patient sitting facing the light—the Surgeon standing in front, elevates the tip of the nose with his thumb to gain as good a view as possible of the polypus; he introduces the forceps closed into the nostril, and approaching the peduncle, opens the blades just sufficiently to slide one above and the other below, and

securely grasps the peduncle. (Fig. 336.) A little movement of the hand will convey the feeling of attachment, while the soft, yielding, texture of the polypoid peduncle, in closing the blades of the forceps, further gives assurance that the spongy bone, a crackling texture, has not been seized. By a gentle pull and jerking twist with the instrument, the

FIG. 336.

polypus is detached and withdrawn from the nostril. Several polypi may successively be removed in like manner, care having been taken to distinctly feel the peduncular attachment before attempting to remove the growth.

This method of extraction is attended with considerable pain, and not inconsiderable hæmorrhage; the latter often compelling the Surgeon to postpone any further removal of the polypi, to a second and a third sitting. Moreover, with due precaution in tearing away a gelatinous polypus, its soft consistence yields, and the tumour is apt to come away piecemeal; or the delicate spongy bone or other basis of mucous attachment is liable to be injured, and it has even been urged that the separation of a small scale of bone with the peduncle will more effectually prevent the recurrence of the growth. This is obviously a pathological error respecting the nature of the ordinary mucous or gelatinous form of polypus; and any extraction of bone should be regarded as a misadventure in the operation which will probably be followed by caries of the exposed osseous surface.

Having regard to all these considerations, the practical importance of which I had often experienced, I, some years since, devised a forceps which cuts and holds the peduncle. The "*polypus scissor-forceps*," as this instrument is named, combines scissors and rasped forceps, one edge of either blade being that of an ordinary scissors, the other broad and rasped. This instrument is, in fact, an adaptation of the grape or flower-scissors, commonly used in conservatories. By means of the scissor-forceps, I have removed nasal polypi in a large number of cases, with comparatively little pain and hæmorrhage; and never, so far as I have been able to ascertain, has there been any return of the growth.

*Ligature* is chiefly appropriate when polypus passes through the posterior nares, and hangs down in the pharynx—naso-pharyngeal polypus.

The object of the operation by ligature is to accomplish strangulation, and thence separation of the polypus in the form of a slough. Accordingly, a loop of firm whipcord, catgut, or silver-wire, is passed through the nostril into the pharynx, and expanded under the polypus, and drawn up around the peduncle, this noosing procedure being aided by introducing the forefinger into the mouth. (Fig. 337.) The ends of the cord, at the

FIG. 337.

nostrils, are passed through a slender, double, canula (Fig. 338), which is then slid along upon them through the nares to the polypus, when, by tightening and securing the ends of cord to the rings at the nasal extremity of the canula, the peduncle of the polypus is strangled. The canula may be introduced threaded with the whipcord, if this seem to be a more easy way of passing the loop. The cord must be tightened, through the canula, from day to day, until separation of the tumour is effected. Sir W. Fergusson recommends separating the tumour at once, when this can be safely done, rather than allowing it to slough away. In either modification of this operation, care must be taken, lest the tumour drop into the lower part of the pharynx or over the larynx, and cause suffocation; and during the process of sloughing separation, the head should be inclined forwards to avoid the risk of fatal systemic infection from the morbid secretion, a result which has actually occurred.

Occasionally, it may be necessary to slit up the ala of the nostril, at its junction with the cheek, in order to gain access to the root of the tumour.

A button-hole-like incision in the soft palate has been resorted to by Maissonneuve, so as to draw the polypus through the opening into the mouth, where it can be ligatured or cut off with the knife. The direction of the button-hole is from before backwards, and the great elasticity of the soft palate readily allows the polypus to pass through a comparatively small opening, which also generally closes without the aid of suture. This procedure—the *bouttonnière palatine*, has yielded the most satisfactory results in the hands of M. Maissonneuve.

A general clearance of the nares has been effected by drawing a plug from behind forwards—a brushing mode of extraction, suggested, I believe, by Dr. McRuer, an American physician, who highly extols it. A

piece of catgut is introduced through the nostrils into the mouth, to which is fastened a piece of soft and dry sponge, corresponding in size, when firmly compressed, to the narrowest part of the nasal passage; it is then drawn gently forwards through the nose. In at least ten cases, all the adventitious growths were thus brought away.

*Fibrous* polypus may, perhaps, be extracted with forceps, or tied when pedunculate. Excision has succeeded in broader-based and larger-sized polypi of this kind.

*Cancerous* polypus is perfectly irremediable and uncontrollable by any surgical proceeding.

**TUMOURS OF THE SEPTUM.**—Besides abscess of the septum, presenting its characteristic swelling as already noticed; certain tumours, containing blood or of a cartilaginous consistence, are liable to form in the septum nasi. The *bloody tumour* is always the result of injury, and has the appearances of ecchymosis in other parts of the body. Absorption of the extravasated blood should be promoted; incision is rarely necessary. *Cartilaginous tumour* is very uncommon. Mr. Ure met with one such case, and wherein he effected a cure by excision; the junction of the ala of the nose with the cheek having been slit up, in order to make room for the application of a gouge to remove the tumour. A *gelatinous tumour*, of uncertain nature, sometimes forms in the septum. It may be obliterated by snipping away a portion of the wall, and cauterizing the interior with nitrate of silver.

*Calculi or Rhinoliths.*—Calcareous concretions occasionally form in the nasal cavities; usually in the lower meatus, or they may originate in the frontal sinus or in the maxillary sinus, and thence pass into the nostril. They vary in size from a date to a hazel nut, or may completely block up the nares, and produce deviation or partial destruction of the septum. They present an uneven surface, and are of a black, gray, or white aspect. Sometimes single, in other cases multiple; nasal calculi consist of phosphate and carbonate of lime, magnesia, and mucus; resembling other concretions. The nucleus may be an extraneous body, as a cherry-stone, or portion of a tooth. The cause of these concretions is obscure, probably chronic inflammation of the Schneiderian mucous membrane. The *treatment* will, obviously, be the extraction of such bodies by suitable forceps or scoop; and then to allay irritation.

**CLOSURE OF THE NOSTRILS** may be congenital, or acquired as the result of inflammatory constriction or adhesion. The ala of the nose may thus be joined to the septum in consequence of ulceration. Any such impediment to respiration and speech, can, perhaps, be overcome by dilatation with tents, gradually increased in size; or it will be remediable by incision, followed by the use of tents, in the nostril.

**PLASTIC SURGERY OF THE NOSE**—or RHINOPLASTIC OPERATIONS.—Plastic or Reparative Surgery comprises all those Surgical operations which are designed and performed for the *repair* of deficiencies of structure,—whether resulting from injury, disease, or malformation. It thus repre-

FIG. 338.

sents a large division of Operative Surgery, contrasting with that which pertains to Operations for the *removal* of parts, as by Excision and Amputation.

Plastic Surgery is well illustrated by rhinoplastic operations; the repair of structural deficiencies in this organ as the result of wounds, having almost given rise to all similar operations in respect to other organs; as principally exemplified by the operations for hare-lip, and cleft-palate, certain diseases of the eyelids, and of the organs of generation. Rhinoplastic operations are sometimes designated Tagliacotian operations, in honour of their originator, Gasparo Tagliacozzi, a celebrated Italian physician who flourished in Bologna, in the latter part of the sixteenth century. After his death, a marble statue was erected to his memory in the anatomical theatre at Bologna, with this insignia of his art—a nose—in his hand.

The entire nose, or a portion only, may require to be re-made; in consequence of destruction by disease or injury, or owing to congenital malformation.

(1) *Nose*.—Restoration of the entire nose may be accomplished by either of two plastic operations. In both the nose is re-made by borrowing a properly-devised flap of sound integument, and adapting it to the remnant organ,—itself in a sound state for its reception; but in one operation—that of Tagliacotius, the flap was taken from the inside of the arm; in the second or Indian operation, the flap is taken from the forehead at the root of the nose. The latter operation is now practised, exclusively. It was introduced into this country by Mr. Carpue, in 1814; who also improved the original proceeding by adding a septum nasi, and by the employment of sutures. He was soon followed in Germany by Gräfe and by Dieffenbach, and since by other Surgeons. In this country, the operation was more especially brought into practice by Mr. Liston, Sir W. Fergusson, and Mr. Skey.

*The Indian operation*.—This operation consists of three distinct procedures performed in succession,

FIG. 339.

at different periods, to complete the result. (1) The dissection of the flap from the forehead, and its attachment to the remnant nose; (2) the detachment of the root of the flap where it is twisted down from the forehead, and the formation of a proper bridge to the nose; (3) the formation of a columna nasi. The *flap* of integument is made thus:—a triangular piece of leather is cut into the shape requisite to form the *alæ* and apex of the nose, resembling the shape of the former nose. This outline model is laid upon the forehead with its base upwards, and its narrow peduncular part between the eyebrows at the root of the nose; and the outline is marked out on the skin with ink. (Fig. 339.) The

cicatrized remnant of the nose is then to be freely but carefully pared. The flap, as marked out on the forehead, must be dissected down; care being taken to make it of uniform thickness, but not to interfere with the periosteum or pericranium; and that the peduncular strip, at the root of the nose, be of sufficient length to allow of its being twisted round without affecting the circulation through it, as the channel through which the supply of blood to the flap alone depends. To facilitate this twist, the incision may be extended a little longer downwards on the side to which the flap is turned. Bleeding having ceased, the flap is brought round and its edges neatly adjusted to the pared margin of the remnant nose, and evenly fixed with sutures. The new nose is to be supported, not stuffed, with a little oiled lint; and wrapped in cotton wool to maintain the circulation. The edges of the wound in the forehead, corresponding to the peduncle, may be united with a suture; the rest of the surface healing by granulation, water-dressing should be applied.

In a few days the nose will have become plump and purplish red; but, this subsiding, union takes place and the organ becomes consolidated.

Then, the *twisted strip* of skin may be cut through, and adjusted evenly. To avoid a pucker, it may be necessary to excise a small portion.

The *columna nasi* is best restored by forming it out of the upper lip, as recommended by Mr. Liston, who practised this procedure with great success. First, the inner surface of the apex is pared. Then, a perpendicular strip is cut out of the centre of the upper lip, a quarter of an inch in breadth, and consisting of the whole thickness of the lip. The frænum having been divided by a touch with the bistoury, this strip of the lip is turned, not twisted up; the labial margin is thinly pared, and the raw surface adapted to that of the apex; the two are retained with a twisted suture, and the edges of the lip-wound brought together by two more such sutures. If troublesome bleeding occur from the coronary artery, one of these sutures should be so placed that the needle shall transfix the ends of the vessel.

During the process of complete restoration, the nostrils must be dilated occasionally, by introducing silver tubes up these passages. Eventually, the exposed mucous membrane of the raised strip of lip acquires a cutaneous character, while the interior of the nose resembles a mucous membrane and is moistened with a mucous secretion. Patients, who had previously been snuff-takers, have enjoyed a pinch of snuff, apparently with as much gusto as the oldest and most experienced nose could possibly have imparted. But even should our constructions fail in enabling a patient to resume a nasty habit, a nose is still a nose, "although there's nothing in't." (Fig. 340.)

FIG. 340.

(2) *Columna nasi*.—This portion of the nose may *alone* require restoration, in consequence of its separate destruction by disease involving the septum. The nostrils thus present one large gap, and the nose becoming depressed,—more so with destruction of the bones—great deformity results. The upper lip also, having lost the support of the columna, becomes pendulous, projecting, and thickened; augmenting the disfigurement. Restoration of the columna may be effected by the operation already noticed as supplementary to that for the nose; by means of a tongue taken from the middle of the upper lip.

(3) *Ala*.—When one ala only is deficient, a flap of integument, suitably shaped, may be raised from the cheek, and adjusted to the part, the edges of which have been previously pared, and retained there by a few points of suture. When both alæ are wanting, or if the cheek be thin, the flap had better be brought from the forehead. The connecting pedicle will necessarily be long and thin; and to maintain the vitality of the engrafted flap, a groove may be made in the dorsum of the nose to receive the pedicle.

(4) *Depressed Nose*.—Depression of the *apex*, or of the *bridge* of the nose, may severally occur; owing to the loss of the septal cartilage, or of the septum and nasal bones,—the fabric of the organ, although the external parts remain entire.

These defects may be remedied, by loosening the alar connexions of the nose, and drawing integument from the cheeks; thus raising the depressed portions of the organ, according to the proceeding of Larrey and Dieffenbach, who revived the operation of Celsus; or by the elevating operation of Sir W. Fergusson,—a simplified modification of that proceeding.

The point of a small scalpel, says Sir W. Fergusson, was introduced under the apex, and the alæ were separated from the parts underneath; the knife was carried on each side between the skin and the bones, as far as the infra-orbital foramen, taking care not to interfere with the nerves; when, by passing the point of my finger below the nose, I caused the latter organ to be as prominent as could be wished. I now passed a couple of long silver needles, which had been prepared for the purpose, with round heads and steel points, across from one cheek to the other, having previously applied on each side a small piece of sole-leather, perforated with holes at a proper distance; then I cut off the steel points, and with tweezers so twisted the end of each needle, as to cause the cheeks to come close to each other, and thus to render the nose prominent. Thus, by bringing the cheeks more into the mesial line, a new foundation, as it were, was given to the organ. Adhesion occurred in some places, granulation in others; in the lapse of ten days the needles were withdrawn, and in the course of a few weeks, when cicatrization was complete, the nose presented as favourable an appearance as could reasonably have been desired.

In all these *opérations de convenance*, and of very uncertain result, “let it”—as Mr. Skey advises—“be the patient who urges the operation.” The responsibility will thus be divided. Sloughing of the new nose, took place in one of Mr. Liston’s early cases; in another, hæmorrhage occurred under the flap, on the ninth day, and more than a pint of blood was lost; while, two patients out of six died, on whom Dieffenbach operated, owing probably to an unfavourable state of constitution.

THE FRONTAL SINUSES are subject to certain diseases not peculiar to

these osseous cavities, but originating in them as the seat of disease. *Abscess* forms occasionally, within the frontal sinuses, accompanied with great pain, of a dull, heavy, aching character; and subsequently expansion of the cavity, followed possibly by caries, and symptoms of inflammation extending to the membranes of the brain. Warm fomentations and other palliative measures may be employed in the first instance; but evacuation of the matter formed will probably become advisable. This would be done by trephining the anterior wall of the sinus, using a small trephine. *Polypus*, of malignant character, springing from within the sinus and expanding the cavity, might perhaps be treated in like manner; the trephine, however, being applied with the view of making an aperture for extirpating the tumour.

## CHAPTER XLIII.

## INJURIES AND DISEASES OF THE MOUTH.

**THE LIPS**—*Wounds* of the lips differ in no way from these lesions in general, excepting the liability of excessive hæmorrhage, compared with the extent of injury, when the coronary artery is divided. The vessel will have to be secured by means of a twisted suture, as for hare-lip; and care must be taken that the needle which brings the surfaces together, shall transfix the lip on either side, so as to command the cut ends of the artery beneath the mucous membrane. It is the arrest of hæmorrhage by acupressure. Otherwise, the blood collecting within the mouth may be swallowed, and thus large quantities of blood have been lost imperceptibly to the Surgeon.

**HARE-LIP.**—This deformity is a congenital fissure of the upper lip, from arrest of development. It is usually situated a little to the left side of the middle line of the lip below the nostril; occasionally, on the right

FIG. 341.

side; in either case forming *single* hare-lip. (Fig. 341.) Two such fissures may be present, one on either side, the central and intervening portion of the lip projecting as a short rounded process; forming *double* hare-lip. (Fig. 342.) In connexion with this latter deformity of the lip, the median portion of the

FIG. 342.

superior maxillary bones, which contains the two front incisor teeth, and which constitutes a distinct bone in the human embryo and in the lower vertebrata—the inter-maxillary or pre-maxillary bone, may be disconnected on one or both sides and project forwards, or depend from the septum narium, as a snout. Fissure of the bony or hard palate or of the soft palate, cleft palate, not unfrequently co-exists with hare-lip; and the median gap in the alveolus, just noticed, may extend backwards into a fissure of the palate. Cleft palate, however, frequently exists without hare-lip.

No particular functional inconvenience attends this deformity, but extensive hare-lip, interferes with the infant's power of suckling.

*Treatment.*—The age for operation—to remedy this congenital defect—has been the subject of much difference of opinion among some of the best Surgeons. There have been successful results at all ages; from a few hours after birth, a few days, weeks, or months, or at a later period, not until after the commencement of dentition. Having regard to the strength of the child, and that no unfavourable condition ensues from some delay; a month or six weeks will probably be about the proper time for operation.

*Operation.*—The child having been swathed in a large towel or piece of sheeting, thus completely securing the hands and feet, it is laid in the nurse's lap, so that the head of the infant shall be secured between the Surgeon's knees. Chloroform may of course be administered, but even then the position of the child, as described, will much facilitate the operative proceedings. Taking the lower corner of one side of the fissure between the thumb and finger and pulling forward the lip on the stretch, the Surgeon just divides the frænum with a straight and narrow bistoury, so as to free the lip; entering the point of the knife at the apex of the fissure, and carrying it forwards to the margin of the lip, the edge of the fissure is pared on that side, and then on the other side, held in like manner; care being taken that the whole thickness of the lip is pared. (Fig. 343). The pared edges are brought together and evenly adjusted, and secured by one or two twisted sutures. (Fig. 344.) The hare-lip pin

FIG. 343.

FIG. 344.

should be entered from one-third to half of an inch from the cut edges, and passed deeply, to about two-thirds, through the substance of the lip, on either side of the fissure. A strong silk thread is twisted round the projecting ends of the pin, over the lip, in the form of a figure of eight. The point of the pin is snipped off with small cutting-pliers, the head of the pin remaining on the other side. A second suture is applied in like manner. It is most important to observe that the line of continuity of the labial margin be maintained, and that there be no angular puckering at the apex of the fissure. No dressing is required.

Certain little modifications of this operation are urged by some Surgeons of experience. Thus, Mr. Skey recommends a slight excurvation of the incision in paring the edges of the fissure; to preserve the form of the lip, which is otherwise liable to be affected by retraction of the cicatrix. When inequality of the fissure exists, Mr. Lloyd was in the habit of preserving a small slip of the flap of the long half of the lip, and of attaching it to the under surface of the shorter half, that there might be no notch or fissure remaining after cicatrization. Mr. Holmes Coote

prefers two fine silver sutures, one at the angle of the fissure and the other at the red of the lip, instead of a second hare-lip pin; the former, it is alleged, holding these parts more immovably in contact.

The time for withdrawing the pins, is, usually, about the fourth day; or the labial one may be left for a day or two longer. The pin must be gently withdrawn, and the twisted thread caked with the oozed blood, should still be left undisturbed on the lip, to which it adheres as a plaster. If this precaution be taken for some days longer, there will scarcely be any necessity that the recently united wound should be supported by "adhesive strapping," or for the use of the spring cheek-compressor devised by Mr. Hainsby. (Fig. 345.)

Fig. 345.

Simple sutures—without the steady support of pins—are in favour with some Surgeons. Mr. Erichsen has treated hare-lip, double and single, in this way, for many years, and most successfully. He, however, restricts the eligibility of this modification of the treatment to cases, unconnected with very wide fissure in the palate, or great inter-maxillary projection. Under these circumstances the pins are preferable.

*Double hare-lip*, without malformation of the upper jaw, is treated on a similar principle. If the central lobe between the fissures be of full breadth and length down to the prolabium, the margins of both fissures should be pared independently, and united separately; but if the central portion be short and rounded, it should be sliced to a point downwards and the pared margins of the lip united, embracing this little V-shaped piece above and coming into contact with each other below. (Fig. 346.) In both cases, the same needles are sufficient to retain the two fissures, by transfixing the central lobe; the threads are wound round as before. Both fissures may be pared and treated thus simultaneously; or at separate periods, in order, it is said, not unnecessarily to increase the chances of failure.

Fig. 346.

The median—inter-maxillary, portion of bone, containing the two front incisor teeth, which not unfrequently complicates double hare-lip, must be dealt with when it projects so as to prevent union of the wound. The projecting portion may be removed with cutting-pliers; or it can generally be made to recede by gentle pressure, in the course of a few weeks—this plan of treatment having the obvious advantage of preserving the incisor teeth. It was strongly advocated by Sir A. Cooper, and is

now generally in favour. Pressure can be applied effectually by means of a spring-truss, worn several hours daily, until the portion of bone is sufficiently depressed to allow the lip to be brought over it into easy apposition.

M. Genzoul seizes the projecting portion of bone, with strong forceps, partially breaks and forces it into the perpendicular; and this immediate mode of replacement has proved successful. If the piece is connected to a perfect septum nasi, it will probably be necessary to remove a triangular bit, base downwards, out of the latter, before attempting to press back the projection.

*Congenital Transverse Fissures of the Cheeks*, extending from the angle of the mouth to the anterior border of the masseter muscle, or up towards the malar bone. Such fissures are rare. They must be treated on the same principle as hare-lip; their edges being pared and brought together by pins and twisted sutures, that union by adhesion may close the fissure.

*Congenital Contraction of the Orifice of the Mouth*, or even complete closure at birth, may be found, as in the nostrils. This condition will tax the ingenuity of the Surgeon to overcome by dilatation, or suitable incisions. The cut edges of skin and mucous membrane should be united by suture.

**CHEILOPLASTIC OPERATIONS.**—Restoration of either the Upper or the Lower Lip may be effected by plastic operations, varying in their design according to the deficiency of structure.

(1) The *Lower Lip*, partially destroyed by disease or injury, admits of restoration from the cheeks, which readily supply both skin and mucous membrane.

The *Celsian* operation, as described by Malgaigne and put into practice by the late M. Bonnet, of Lyons, is simply this:—The affected part of the lip, as in the case of cancer, having been removed by a **V**-shaped incision, or by two vertical incisions down to the base of the jaw, united by a transverse incision; the cheiloplastic operation of restoration will vary accordingly.

When a *triangular* portion of the lip and chin has been removed, this deficiency may be repaired by a transverse incision from the angle of the mouth, on each side, into the cheek, thus completing the boundaries of two triangular flaps. The margins of the **V**-shaped incision are then united by suture; while any portion of the upper border which may not be required for the formation of the new lip, from out of the cheek, is united to the part with which it is in contact. The mucous membrane in the mouth should be united to the skin by fine sutures. When the loss of substance is *quadrilateral*, two other incisions, parallel to the two prolonging the angles of the mouth, must be made along the base of the jaw. The two quadrilateral flaps, thus marked out, are then dissected from the bone, and brought forward, union in the middle line being obtained by sutures, as in the former operation.

Mr. Syme's operation consists in removing the cancerous ulcer by a large **V** or triangular incision, extending from the angles of the mouth to the chin. The apex is then the starting-point of an incision on each side, obliquely downwards and outwards, *under* the body of the jaw, and terminating in a slight curve outwards and upwards. The flaps, thus indicated, are dissected outwards, and raised upwards, until the original triangular incision comes into a horizontal line, forming the margin of the new lip, the secondary incisions under the jaw coming together in a

vertical direction, where they are retained by twisted and interrupted sutures.\*

Dr. Buchanan of Glasgow, in 1841, had devised a similar operation :—The diseased portion of lip having been removed by an *elliptical* incision, extending from angle to angle of the mouth, an incision is then carried downwards and outwards to the chin, on each side; and from these points an incision is made upwards and outwards, on each side, on the body of the jaw, parallel to and corresponding in length to the elliptical incision below the lip. The flaps, having been dissected, are raised to a horizontal line, and the secondary incisions united, as before.

This operative procedure may surpass Syme's, when the incisions are required to meet the removal of a large, elliptical-shaped, portion of substance, comprising the whole lip from side to side; but it will, otherwise, be desirable to have the incisions as little on the face as possible. All these plans of cheiloplastic operation for the lower lip are, however, superior to that of Chopart's operation, whereby the flaps of integument were raised from below the jaw, even as low down as to the hyoid bone.

(2) The *Upper* lip less frequently requires restoration, its structure being comparatively seldom the seat of cancer-growth.

Shrinking of the upper lip sometimes ensues from profuse salivation, by which this part is tightly stretched over the alveolar arch, and perhaps adherent to the gums.

Von Ammon rectifies this condition by the following plastic operation :—The lip is first detached from the gum, then an incision is carried upwards from the angle of the mouth, for about an inch and a half, towards the ala nasi. The tense parts separate, and this longitudinal fissure assumes a triangular shape. A flap of integument is dissected from the cheek, and brought down to occupy the space at the angle of the mouth. Precisely the same operation is performed on the opposite side.

The *central* part of the lip may be destroyed, and the two adjoining portions become drawn up towards the septum and alæ nasi, exposing the incisor teeth.

Dieffenbach rectified this deformity by bringing a sufficient amount of integument from the adjacent substance of the cheeks, on each side. An incision by the side of the alæ nasi, is carried round to the middle line of the lip, and down through its margin; each half is loosened, and brought together with twisted sutures.

DISEASES.—*Hypertrophy* of one or both lips sometimes accompanies the irritation of a crack or fissure, or it remains after the fissure has healed, and the source of irritation apparently has ceased. In the one condition, the fissure should be treated on ordinary principles, that the hypertrophied enlargement may subside; or, this remaining, an elliptical portion of the mucous membrane of the lip may be excised, and the wound united by sutures.

*Ulceration* of a simple character, though, perhaps, chronic, is liable to occur on any part of the labial mucous membrane; either as a result of the irritation of a sharp portion of tooth, or of a false tooth, or in connexion with a disordered state of the stomach and bowels. The treatment having reference to these causes, will be, to remove any source of irritation, oral or gastro-intestinal, and to touch the ulcer with nitrate of silver.

TUMOURS.—The *lower* lip is more commonly the seat of various forms of tumour.

\* Edin. Month. Journ. 1347.

*Encysted* tumour, small and semi-transparent, and containing a glairy fluid, resembles ranula in appearance, but that swelling is situated under the tongue. Excision of the cyst, by careful dissection, is the most certain cure; or snipping the cyst, and freely cauterizing its interior with nitrate of silver, may not be followed by a return of the tumour.

*Erectile* tumour of the lip admits of removal by excision, ligature, or strong cauterization. The size and situation of the growth will determine the choice of these modes of treatment.

*Epithelial Cancer*, affects the lower lip, very rarely the upper lip.

FIG. 347.

Commencing, as a small warty growth on the lip; or as an indolent tubercle; or as an excoriation of the mucous membrane, surrounded by an inflamed and thickened base; the disease is primarily situated in, or just beneath, the skin or mucous membrane, at or near the junction of the two in the red margin of the lip. Spreading thence, the wart grows in breadth and thickness, the tubercle peels and ulcerates, or the excoriation deepens. Eventually, the ordinary characters of epithelial cancer are presented. (Fig. 347.) The sub-maxillary glands become involved, and thence enlarged and indurated. The ravages of the disease, as it is seen to occur in other parts, may here also ensue; ulceration destroying the lip, and the lower jaw-bone and teeth becoming carious.

Pain, and discharge sometimes wear down the patient.

The diagnosis from *chancre* of the lip, is mainly determined by the latter presenting a superficial ulcer, raised on a base of cartilaginous hardness; the sore may cicatrize, and the indurated base remain. The sub-maxillary glands enlarge at an early period, six or eight weeks after the sore commenced. Secondary symptoms appear sooner or later, unless early treatment has been adopted. The upper or lower lip may be equally often the seat of chancre. Cancer of the lip occurs almost exclusively in men, and after the middle period of life; in these two particulars also it probably differs from chancre.

The local and exciting cause of cancer, would seem to be some source of irritation; commonly the adhesive contact of a clay-pipe when not coated with sealing wax; or a sharp broken tooth.

*Treatment.*—*Excision*, free and early, is the only cure. Some affection of the sub-maxillary glands does not forbid this procedure; but they also should be extirpated. The incisions in the lip must be directed according to the line of disease. A V-shaped incision will best include the diseased portion when it extends downwards in the lip (see Fig. 347); a quadrilateral operation in other cases; or a more superficial semicircular sweep, when the disease extends along the lip. The lines of incision should be brought together with twisted sutures, as in the operation for hare-lip; a horizontal incision may be closed by simple sutures, uniting the opposed edges of skin and mucous membrane.

This operation sometimes proves permanently successful; but often the disease returns in from six months to two years. Excision should, however, be repeated, to prolong life.

*Plastic* operations, as already described, may be resorted to, for restoring portions of the lip which have been thus sacrificed.

Very rarely, other forms of cancer affect the lip, and more often, the upper lip.

THE CHEEKS.—*Wounds* of the cheeks offer nothing worthy of special notice, in respect to the nature of these lesions. They must be neatly united, by means of simple sutures or hare-lip pins and twisted suture.

*Salivary Fistula* is a perforation or division of the Stenonian duct of the parotid gland, whereby the saliva dribbles out on the cheek. This condition may result from wound of the cheek, sometimes in removing a tumour situated over the duct; or in consequence of abscess or ulcer of the cheek, implicating the duct. The fistulous aperture and trickling saliva are a source of great disfigurement and inconvenience.

*Treatment*.—The object is to restore the continuity of the duct, as the natural channel for conveying the saliva into the mouth; where it opens upon the inner surface of the cheek, by a small orifice, admitting only a very fine probe, opposite the crown of the second molar tooth of the upper jaw.

Recent salivary fistula may sometimes be closed by pressure alone, by means of a compress applied over the fistulous aperture in the cheek; the saliva resuming its natural course through the duct, which still remains open. I have thus cured a fistula of this kind, in two instances. In a more established condition, the edges of the external aperture should be pared and brought together, and then pressure applied. *Confirmed* salivary fistula, is probably attended with closure of the natural opening into the mouth. It will be necessary to form an artificial communication with the duct; and this may be done, either by passing a small seton from the inside of the cheek into the fistula, as Desault recommended; or by introducing a wire, red-hot, or heated by galvanism, as Mr. Marshall has suggested. The external fistulous opening must then be pared and closed with a twisted suture.

DISEASES.—*Tumours*.—Various species of morbid growths form, occasionally, on, or in the cheek; fatty and fibrous tumours, as I have seen in two cases; cartilaginous, cystic, and cancerous; or vascular and erectile tumours.

The removal of any such tumour can generally be accomplished by careful excision, having regard to the thickness of the cheek and the relation of the growth to surrounding parts; or, the subcutaneous application of ligature will probably be available, in the case of an erectile tumour. It is sometimes remarkable how much the cicatrix, after such operation, becomes effaced in the course of years.

*Corroding Ulcers* of the Cheek, may occur in two forms. *Lupoid* ulcer has all the characters of this form of Ulcer; the hollow excavation, absence of granulations, thin, worm-eaten and everted margin—thus contrasting with a cancerous ulcer. The ravages of lupoid ulceration are equally notable. The features disappear as the ulcer extends; the nose and mouth may fall into one cavity and the eye drop down from the orbit, exposing the back of the pharynx, nares, antrum and interior of the orbit, in one large, irregular and carious-bottomed excavation; which completely disguises any recognition of the individual face, or even obliterates its form as that of the human face. Such a result had occurred in a poor person, who, if I remember rightly, was found on a door-step one night, many years since; and a wax-model of whose

horribly remnant face is deposited in the Museum of the University College, London.

The *treatment* of this form of Ulcer is noticed under Lupus. Chloride of zinc in paste, well applied to the excavation, is far more effectually curative than excision. This I once saw in a case treated by Mr. Liston, and similar results were obtained by Mr. Moore, in two cases. In one of these, the surface was known to have remained perfectly healthy two years and a half afterwards; although the disease had destroyed the greater part of the contents of the right orbit, the eyelids and skin in the neighbourhood.

*Cancrum oris*.—Another form of corroding ulcer, a phagedæno-gangrenous ulceration affecting the inner surface of the cheek and lip. Commencing, usually, with a brawny, tense, shining swelling of the cheek; the corresponding interior of the cheek soon presents a deeply excavated, round ulcer, having a brown, pulpy, sloughy surface. Differing somewhat from this typical condition of the disease; it may commence, in its most rapid form, as a black gangrenous spot, unaccompanied by any surrounding inflammatory swelling; or, in a milder form than usual, it presents a shallow, ash-coloured ulcer, situated on the inside of the lip, more often the lower one, and extending to the cheek. This latter form of the ulceration seems to have a diphtheritic character.

The disease may extend considerably; the excavated ulcer inside the cheek perforating and opening in the form of a circular dark-coloured gangrenous cavity, communicating with the mouth. The gums are turgid and spongy; while a fœtid saliva and putrescent discharge dribbles from the lips. Comparatively little pain attends the process of destruction; but the constitutional exhaustion is often fatal, and the patient sinks in a comatose state.

The *cause* of cancrum oris is general debility; resulting from poor living, among the ill-fed and otherwise destitute children of large towns, who are chiefly affected. Or, the disease may be a consequence of one of the eruptive fevers, as measles or scarlatina, or any other severely reducing illness; and occasionally, it has followed the prolonged administration of mercury. The feeble, wan, abject aspect of the poor little victim, will be readily associated with the characteristic appearance of the buccal or labial ulceration.

*Treatment*.—Local applications must be employed to arrest the disease, and correct the fœtid, self-poisoning discharge. Hence, the nitrate of silver should be freely applied, or the strong nitric acid will probably be necessary; and the mouth should be syringed with chlorinated solutions. But the constitutional treatment is most curative; and, quinine and ammonia, the latter not pushed to its depressing effect, with wine, beef-tea, and other nutritious food, are the most efficient measures. Chlorate of potash in large doses, is said to have an almost specially remedial influence. My own experience does not enable me to confirm this view.

The deformity resulting from cicatrization, may require some plastic operation for its rectification.

*TONGUE*.—*Wounds*.—Severe hæmorrhage, principally from the lingual artery, is the chief point of practical importance, in wounds of the tongue. The lesion itself is apt to occur by an accidental bite of the tongue, and not unfrequently severe laceration is thus occasioned during an epileptic fit. When the organ is protruded, a blow on the lower jaw has been known to nearly sever the tongue; as happened in the case of a patient of mine, to which I have particularly alluded in illustration of the general law of

primary adhesion, and a similar extent of lesion has occurred from a blow in a prize-fight.

*Treatment* must first be directed to the arrest of hæmorrhage, which may be effected by ligature or torsion of the lingual artery; any oozing of blood being then restrained by means of ice-water held in the mouth and repeatedly renewed. The divided parts may be adjusted with sutures; which, however, speedily separate, and union will probably as speedily take place. It is a remarkable fact, how much the sense of taste is gradually restored; showing that the gustatory nerve, when divided, reunites without apparently any interruption in the continuity of its nerve tissue.

*Foreign Bodies* are sometimes thrust into the substance of the tongue, and may even become embedded and concealed. In the Museum of Guy's Hospital, there is a specimen (1674) showing a piece of tobacco-pipe, over which the substance of the tongue had closed. Frequent hæmorrhage occurred, and ultimately proved fatal.

In any case, the foreign body should of course be removed, if possible.

*Tongue-tie* signifies a congenital shortening of the frænum linguæ, whereby the apex of the tongue is depressed and restrained; so that it cannot be protruded beyond the incisor teeth, and there is difficulty in suckling, and eventually indistinct articulation in the adult.

This defect can easily be remedied, by snipping the bridle across with blunt-pointed scissors; observing to direct their points downwards just to avoid the ranine arteries. Not unfrequently, mothers request such relief very unnecessarily.

*Prolapsus* of the tongue may undoubtedly occur; it having been noticed by Zacchias in 1628, Bertholin, Sauvages, Percy, Laurent, Mirault, Maurant, Lassus, Crosse, and Professor Humphry. In a case recorded by the latter author, the organ was enormously enlarged, both in circumference and length; the portion immediately within the lips having five inches circular measurement, and when the tongue was drawn into the mouth as far as possible, the length from the upper lip to its tip, measured two inches. The protruded organ had been habitually suspended in a bag from the head. It was soft and supple, but of a granular or warty appearance, with deep clefts, owing to hypertrophy and separation of the papillæ; the colour remaining natural. The opening of the mouth was enlarged, the lower lip everted, and the angles of the mouth depressed; elongating and giving a peculiar expression to the face. The orifices of the sublingual ducts, also enlarged, were situated just in front of the edge of the lip; and thence the saliva dribbled continually from the end of the tongue, to the amount of more than half a pint daily. The mental portion of the jaw and inferior incisor teeth, had become everted by constant pressure of the tongue, forming a curvature in which the organ lay; and a wide interval also between the teeth, which, even when the mouth was closed and the molars were in contact, was nearly two inches in extent between the upper and lower incisors.

This condition of the tongue may be congenital, or acquired as a consequence of profuse salivation. It is attributable to hypertrophy, or possibly to a paralytic state of the retractor muscles of the tongue.

The *treatment* of prolapsus linguæ is unsatisfactory. The protruding portion may be removed by excision, a perilous and even fatal adventure; or by ligature, with the formation of a poisonous slough, for a while, in front of the mouth and nostrils; or by means of the écraseur—a mode of

excision and rapid strangulation, thus avoiding the risk of hæmorrhage and slough. Pressure has caused the swelling to partly subside, but it has returned again.

**DISEASES.**—*Glossitis*.—Acute inflammation of the tongue is attended with sudden enlargement of the organ, which protrudes from the mouth, presenting a red mammillated appearance, with profuse salivation; while the patient can neither speak nor swallow, or scarcely breathe. It occurs rarely as an idiopathic affection, sometimes as a consequence of over-salivation from the abuse of mercury. *Treatment* is urgent, and the tension resulting from infiltration of serum and from congestion can be at once relieved by a free incision on either side of the raphe, along the dorsal aspect of the tongue, thereby avoiding the ranine arteries. But it should be remembered that the œdema may so far involve only one side of the tongue as to cause the lower surface, which swells more readily, to be turned directly upwards; the incision made above passing into the tissues naturally inferior, and which would resume this position as the swelling subsides. Tracheotomy may have to be resorted to for the relief of dyspnœa. Saline purgatives will however usually complete the reduction of the swelling, when they can be swallowed, after the immediate relief afforded by incisions. Astringent and cleansing gargles are also useful adjuncts.

*Abscess* of the tongue—should it occur—may be detected on careful examination of the deep-seated semi-elastic, and fluctuating swelling. It must be punctured as soon as possible.

*Ulceration* is liable to occur, in a simple form, as the result of irritation by decayed teeth; or in a specific form, as a manifestation of secondary syphilis. Fissures and milk-white stains on the dorsum of the tongue, coupled with the history of syphilis; will determine the diagnosis. The *treatment* varies of course with the cause; the removal of a decayed tooth, and aperient stomachic medicines, may prove sufficient to heal the ulcer; or, it must be treated as a secondary form of syphilis, by the topical application of nitrate of silver with the administration of iodide of potassium and bark.

*Syphilitic tubercle*, and *Psoriasis* of the tongue, mostly having syphilitic origin; must be treated in like manner.

**Tumours** (1) *Cancer* of the tongue may occur in, perhaps, three forms. *Scirrhus*, commences as a firm, incompressible knob on the edge of the tongue, and situate often opposite the last molar or wisdom tooth. Considerable pain and difficulty are experienced in moving the organ and in deglutition, and pain darts along the Eustachian tube towards the ear. The saliva flowing from the mouth, and fœtid secretion accumulating in the throat and exciting cough, combine with the pain, sleeplessness, and want of nourishment, to reduce the patient. At length, a deep excavated ulcer forms, and hæmorrhages occasionally supervene. The submaxillary glands become affected; presenting first, a circumscribed and then a diffused tumour in the neck, covered by reddened and thinned integument; this also ulcerates and discharges a thin fœtid fluid, with occasional hæmorrhage. Emaciation and cachexia supervene according to the duration of the disease. Death took place in ten months, from arterial hæmorrhage, in the case of the late Bransby Cooper. A deep excavation was found at the root of the tongue and the tissues around, extending to the muscles about the hyoid bone, and the adjoining lymphatic glands were infiltrated with cancer.

*Soft cancer*, in the form of an irregular lobulated mass, of reddish-brown colour with vascular red points, and of a spongy succulent character, was the kind of malignant disease in a case recorded by Mr. Ceely of Aylesbury. The tumour protruded from the mouth, and a large portion weighing seventeen drachms and a half, was easily peeled off, exposing a large jagged surface covered with coagula. But the hæmorrhage was moderate, and soon repressed with matico powder. The growth returned within a week, yet the man was still alive thirteen years after the operation.

*Epithelial cancer* forms not uncommonly on the tongue, as on the lower lip. It presents an opaque white raised patch, consisting of matted epithelial scales, which becoming detached at length exhibits an ulcer of irregular surface, with hard everted edges produced by epithelial infiltration around the ulcer. Co existing with such a patch or ulcer on the dorsum of the tongue, I have seen two more buttons on the hard and soft palate. Considerable pain may be experienced, but the functional inconvenience will depend on the situation and extent of the part affected. The sub-maxillary glands sometimes remain unaffected. The disease progresses slowly, in one case existing twelve years, in another sixteen years. The particulars of both these cases are given in Holmes's Surgery, by Mr. Holmes Coote, who regards the disease as not of a cancerous nature.

*Treatment*.—Any cancerous disease of the tongue must be extirpated by surgical operation; no known medicinal treatment having any curative effect. The extirpation must be carried freely around the cancerous infiltration, to lessen the probability of the disease recurring. This may be accomplished by excision with the knife, or by ligature.

*Excision* may be either partial, or complete removal of the whole tongue. The former procedure is appropriate and practicable when the disease is limited to the tip or anterior portion of the organ; the latter operation, becomes absolutely imperative, as the only chance of safety, when the disease is more extensive.

*Partial excision* is easily performed. The patient being seated in a chair with the head supported, and, more conveniently, not under the influence of chloroform; an assistant draws the tip of the tongue forward and retracts the cheek. The Surgeon then seizing the whole tumour within the blades of double-hooked forceps, passes a blunt-pointed bistoury around it, and by almost one sweep of the knife removes the mass. If the operation be incompletely performed at once, the hæmorrhage will preclude a satisfactory examination of the remaining portion of the tongue. If the lingual artery be wounded, this vessel must be commanded by a ligature or torsion; any further hæmorrhage can generally be restrained by ice. The cut surface soon heals, leaving a puckered cicatrix, which is distinguishable from reproduction of the disease by the absence of induration.

*Complete excision* of the tongue. Large portions of the tongue have been successfully extirpated by Regnoli's operation;—simply an incision into the floor of the mouth, extending, under the jaw from one angle of the bone to the other; a vertical incision in the middle of this, from the hyoid bone forwards, will enable the tongue to be more readily drawn downwards through the opening, and nearly the whole organ can then be removed.

Syme's operation, for complete extirpation, consists, in making an incision through the middle of the lower lip and carrying it over the chin

down to the hyoid bone; the symphysis of the jaw is sawn through, and the mylo-hyoid, genio-hyoid and genio-hyoglossi muscles separated; the two halves of the bone are drawn asunder, and the larynx is drawn forwards, thus exposing the whole tongue down to its very root,—the hyoid attachments. The organ is then to be completely excised. Mr. Fiddes of Jamaica, subsequently performed this operation, and recommends that the lingual artery should be ligatured and divided on either side, separately; in order to reduce the amount of hæmorrhage.

*Ligature.*—Portions of the tongue have been removed by ligature, in preference to excision. The risk of hæmorrhage is thus diminished or avoided; but the operation is more painful, tedious, and prejudicial in consequence of contamination during the course of sloughing. To obviate the first objection, and check the profuse secretion of saliva, Mr. Hilton has proposed and practised section of the lingual nerve, prior to the application of ligature. No sensation from the tumour can then be conveyed along the nerve; no reflected irritation can reach the collateral branches of the fifth nerve; no stimulus to an increased secretion of saliva can be given to the salivary glands. Eminently, therefore, an operation based on a physiological principle; the patient should speak more freely, and swallow with less difficulty, should be relieved of pain in the tongue and jaw, temple and crown of the head, and of the incessant inconvenience arising from the dribbling of saliva; he should sleep better, and become better nourished than before. Mr. Hilton sought for the nerve in the floor of the mouth, and exposed it by an incision along the mucous membrane close to the sub-lingual gland. Mr. Moore, who has more recently divided the nerve, takes the last molar tooth as his guide, where the nerve coming forward from under the internal pterygoid muscle is covered only by the mucous membrane. Passing a curved bistoury into the mouth and behind the last molar tooth, an incision three-quarters of an

FIG. 348.

inch long down the jaw, and across the course of the nerve, must divide it. Ligature of the corresponding lingual artery has been combined with this operation by Mr. Moore, in order to cut off the supply of blood to the affected part.

Ligature of the affected part may be performed as for nævus; care being taken to plant the operation sufficiently wide of the disease, and to strangle the mass effectually and completely. (Fig. 348.)

A diseased part of the tongue, situated far back in the organ, has been reached by a vertical incision under the jaw, between the genio-hyoid muscles; and thus Cloquet and Arnott have succeeded in passing ligatures, by means of long needles, through the tongue, and strangling the mass.

The *écraseur* has been recommended by M. Chassaignac for the removal of portions of the tongue; but, while thus reducing at least the risk of hæmorrhage, and avoiding the contaminating influence of sloughing, this mode of combined excision and strangulation

has not found much favour in this country. The instrument is introduced through the tongue, which is drawn out of the mouth, or by an incision under the jaw for the passage of the *écraseur*. It should be worked slowly; two minutes being allowed to elapse between each movement, the transverse division of the organ was effected in half an hour. A second chain is required to free the severed tongue from its muscular attachments; the double operation extending to an hour for its completion.

(2) *Erectile Tumour* or *Nævus* of the tongue is an uncommon form of growth, and does not attain to a great size. Removal can be effected by excision, or, preferably, by ligature; and it may be necessary to reach the affected portion of the tongue through an incision in the mylo-hyoid region.

(3) *Fatty tumour* has been known to occur, either in the substance of the tongue or underneath the organ. In the Museum of the Royal College of Surgeons there is a specimen, No. 190, of fatty tumour taken from the one situation; and Mr. Paget removed another, oval and bilobed, tumour, also from the substance of the tongue, near the apex, where it had been growing for three years. In the Museum of the Middlesex Hospital, there is a fatty tumour, one and a half inches long, which was removed from beneath the tongue, where it looked like a ranula; and a lobulated tumour was removed from the same situation by Mr. Liston.

(4) *Ranula* is a semi-transparent, bluish-white, fluctuating, cyst-like, swelling; situated under the tongue, to one side of the frænum, corresponding to the position of the sub-maxillary gland. The swelling is attributed to a dilatation of the duct—Whartonian duct, of this gland, which forms a sacculated enlargement. This origin is doubted by Mr. Erichsen; but in one case, under the care of Mr. Lawrence, the little finger could be inserted for a short distance into a cylindrical tube, pursuing the normal course towards the gland; and in another instance Mr. Holmes Coote removed a phosphatic concretion, about the size of a pea, from Wharton's duct, thus indicating the mode of origin of ordinary ranula. It disappeared in a few days.

*Cysts* may form, in the same situation, from, perhaps, four sources—(1) dilatation of Wharton's duct; (2) dilatation of one of the sub-lingual ducts; (3) enlargement of a mucous follicle; (4) enlargement of a bursa mucosa, said to exist on the outer surface of the genio-hyoglossus muscle.

The same symptoms arise from any such swelling; the tongue is pushed upwards and backwards, interfering proportionately with speech and deglutition, as ordinary ranula attains the size of a walnut or pigeon's egg. An enlarged bursa presents an elastic swelling more under the side of the jaw, and which attains to a larger size, that of an orange or larger. The contents of these cystic swellings differ; a dilated Whartonian duct or an ordinary ranula contains a clear, glairy, fluid, like white of egg, with, occasionally, perhaps, phosphatic concretion; an enlarged mucous follicle is filled with a putty-like matter consisting of epithelial scales with granular fat; while an enlarged bursa contains a clear, serous, fluid, occasionally tinged with blood.

*Treatment.*—Ordinary ranula may be made to disappear by introducing two or three threads of seton through the front of the sac, the ends are loosely tied, cut off, and the seton left in the mouth. Or, the sac may be snipped with scissors, making a button-like aperture, and the interior touched freely with nitrate of silver.

Mucous cysts are generally loosely attached, and can be dissected out

entire. Enlarged *bursa*, presenting in the neck, can be evacuated by a trochar, and injected with dilute tincture of iodine. Or the seton may be here employed; and Mr. Skey passes it through the floor of the mouth to the most dependent part of the cyst.

GUMS and TEETH.—DISEASES.—*Alveolar Abscess*—*Gumboil*, or *parulis*, as it is technically named, is the simplest and commonest form of this abscess; occurring as an abscess of the gum around a tooth, usually carious. Alveolar Abscess may be described—according to Mr. Salter's definition—as a suppuration around the fang or fangs of a tooth, which is usually carious, accompanied by absorption and expansion of the bony walls of the alveolus or alveoli, and the enlargement of the little pus-sac; the matter gradually finding its way to the surface, either along a canal by the side of the fang of the tooth and opening at the edge of the gum, or through the gum itself at a point corresponding to the end of the root or roots of the tooth implicated. When, however, the fangs are unusually long, or the reflection of the mucous membrane from the gum to the cheek or lip is very superficial, the matter may burrow still more outwardly, and find its exit upon the surface of the face.

An alveolar abscess about to burst externally, presents certain characteristic appearances—the integument becomes firmly glued down to the bone around the spot where the matter ultimately points; the area within this space is red, distended and glistening; the skin becomes thin and papery, and the cuticle scales off. If the surface be kept dry, the abscess often remains stationary for some time; at length; it bursts through a jagged opening, which soon changes into a small, fistulous, orifice, encircled by a pouting lip of granulations. The lip of granulations may be elongated into a papilla, even more than half an inch in length; and closing for a time, it bursts again, as matter reaccumulates. This papilla will return repeatedly after excision by the knife, until the cause in operation—the carious tooth, is itself removed. The *situation of the opening* is diagnostic of the source of abscess—the particular tooth affected. In the upper jaw, alveolar abscess appears upon the cheek at a point corresponding to the extremity of the tooth's fang, under the edge of the malar bone; in the lower jaw, it forms along the edge of the jaw below the buccinator muscle when the molars or bicuspid are its source; and when proceeding from the inferior incisors (canines also?), it points generally beneath the chin, a large pad of granulations forming, the size of a thumbnail, from the centre of which the discharge issues. Abscess associated with the upper incisors or canines never, perhaps, points upon the surface of the cheek; while that of the bicuspid, first and second molar, and all the teeth of the lower jaw, may produce this form of the disease. In children with the milk-teeth, alveolar abscess seldom, if ever, opens externally.

The *diagnosis* of alveolar abscess, as above determined, is important; not to mistake it for diseased bone, nor to attribute an abscess to carious teeth, which may be coincident, but not the cause.

*Treatment*.—Warm fomentations afford relief and bring the abscess forward; an incision through the gum or cheek will then evacuate its contents; but extraction of the diseased or dead tooth is the only certain cure. Two conditions only forbid this curative treatment; an hæmorrhagic diathesis, leading to protracted bleeding after the extraction of a tooth; and abscess associated with the upper incisor teeth in young persons, where the jaw has not yet assumed the adult form, and permanent denti-

tion is incomplete. Extraction of the incisors would then be followed by such contraction of the maxillary arch, as might render it impossible to replace the natural teeth by corresponding artificial teeth.

*Ulceration.*—The gums may present one or more ulcers as the result of alveolar abscess, or they are liable to undergo ulceration in consequence of various constitutional conditions—syphilis, excessive mercurial salivation, and the eruptive fevers.

Treatment consists in tonics, principally bark and the mineral acids, the regulation of the digestive organs, and the local application of nitrate of silver; with chlorinated and astringent gargles.

*TUMOURS.*—(1) *Epulis.*—This is a simply fibrous, or a myeloid and recurring form of growth, springing apparently from the gum, but actually more deeply, from the periosteum of the alveolus, externally, or internally within the tooth-socket. The adjoining bone is very vascular. Presenting, usually, at the edge of the alveolus, between two standing teeth, and more commonly on the labial or buccal aspect than towards the tongue; the tumour grows slowly, displacing and loosening the teeth, and somewhat expanding the alveolar border. It is broad-based (Fig. 349), slightly lobulated, firm, and elastic, smooth, red, painless, and little inclined to bleed, resembling the adjoining gum. It attains to a limited size, varying from a pea to a walnut or larger, or possibly to a remarkable size, with protrusion, and presenting an everted appearance. The upper jaw is more frequently the seat of epulis than the lower jaw, in, perhaps, the proportion of two to one.

FIG. 349.

The *diagnosis* of this kind of growth is simple; hypertrophied gum, in the form of loose flaps and masses, known as polypus and fungus of the gum, and occurring in connexion with decayed teeth; exhibits the only appearance with which the growth can possibly be confounded. The relation of epulis to the presence of teeth, as a cause, may be thus stated. Generally, making its appearance where there are teeth, the growth usually invades one, far more than the adjoining teeth; although caries of that tooth has no apparent causative influence, and occasionally the tumour appears in an edentulous portion of gum.

Ulceration of the surface of the tumour and discharge may ensue, but these or other changes seem to result from external agencies.

*Treatment.*—Early and complete extirpation with the knife, is the only permanent cure. This is accomplished by extracting the tooth or teeth, excising the tumour clean down to the bone, and then removing with cutting-pliers or small saw, the portion of alveolar process corresponding to the base of the growth, and whence it sprang. After having thus performed the operation, I have never yet seen epulis return. In a recent case, where the epulis had been simply *shaved* off, the growth had returned, although originally a small one, involving only the left middle incisor tooth; but upon removing this tooth and a portion of the alveolus by a V-shaped incision, including the tumour, it had not returned some months after the operation.

(2) *Congenital hypertrophy* of the gum and alveolar borders of the

maxillæ—has been met with, by Mr. Pollock at St. George's Hospital, in 1859, and a similar case was first described and figured by Professor Gross, in the Second Edition of his *System of Surgery*. The tumour-like growth was identical in both cases. A large mass, pink and smooth, protruded from the mouth; it was very hard, inelastic, slightly lobed, and insensitive. It consisted of an expanded and prolonged development of the alveolar borders and an immense thickening of the fibrous tissue of the gum, with a proportionately exuberant growth of the papillary surface, covered by a very thick and hard epidermis. The papillæ were enormously lengthened, so that when the epiderm was removed, they stood up like the pile of plush or velvet, and could be brushed from side to side with the finger; this papillary hypertrophy being distinctive of the tumour-like outgrowth. The gums of both jaws were affected, more so the upper jaw, and most enlarged in the front of the mouth where it overlapped the edge of the lower jaw. The coincident early cutting of the teeth, one tooth having appeared a fortnight after birth and six by the fifth week, together with a large quantity of hair on the head and body; would seem to indicate a tendency to a general tegumentary hypertrophy. At birth however, the mouth was natural, but in five or six weeks, the gums had become full and thick.

The *treatment* adopted, was partial and repeated removal of the projecting mass, until the alveolar borders were reduced to within moderate limits. A slight tendency was evinced to return of the hypertrophy.

(3) *Polypus*.—The gum is liable to a simple hypertrophy, as an outgrowth, in the form of mucous tubercle; affecting the gum-structure alone, and not involving the osteal membrane, nor complicated with a growth of the alveolar border of the jaw. The seat of this affection is mostly, the little tongues of gum between the teeth, particularly towards the front of the mouth; these portions of gum growing up, perhaps, so as to partly cover the crowns of the teeth. An uncleanly state of the teeth, allowing the accumulation of tartar, is usually associated as the cause of this hypertrophy; or it may be a syphilitic condition.

*Treatment* consists in simply cleansing the teeth with a tooth-brush, using an astringent tooth-powder, and a similar lotion of tannin or permanganate of potass. Tartar must be removed by properly scaling or scraping the teeth. A carious tooth should be extracted, filed down, or plugged. The polypoid gum-structure may have to be extirpated. A syphilitic taint will require the appropriate constitutional treatment of this disease.

(4) *Vascular Tumours*.—Nævus and aneurism by anastomosis occur, sometimes, about the necks of the teeth; more commonly in front of the upper jaw, between the incisors, or canines and lateral incisors. Springing, apparently, from spongy vascular bone; the tumour attains a variable size, about that of a marble, with a somewhat constricted base; it has a purplish colour, is elastic and compressible, becoming reduced in size and pale on pressure, it regains its previous characters in a pulse or two; and there is a constant throbbing sensation without pain. Oozing hæmorrhage proves troublesome from time to time, and even dangerous during sleep, the blood trickling into the glottis. The whole of the gums are turgid and red. These tumours have been observed more frequently in adult and middle life; they are perfectly innocent, and evince no tendency to return, when eradicated.

The *treatment* must be removal by ligature or excision; preferably in the latter way, including the bony base of the tumour. Hæmorrhage can be restrained by cold and pressure, and if profuse for a minute or two, it soon ceases.

**TEETH.**—**INJURIES and MISPLACEMENTS.**—*Fracture and Dislocation.*—A portion of a tooth may be broken off, without exposing the pulp cavity; the fractured surface should be filed down smoothly. With exposure of the pulp cavity, as when a tooth is broken off at its neck; pain and inflammation may be subdued by anodyne applications or by destroying the nerve. It may become necessary to extract the tooth. A loosened tooth should be braced to a neighbouring firm tooth with silver wire. A tooth, knocked out of its socket, has been replaced, and has permanently retained its hold.

*Eruption of Milk-teeth.*—Swelling and tenderness of the gums always attend the natural process of teething; eruption of the teeth may, however, be readily facilitated and the accompanying symptoms relieved, by means of the old-fashioned coral, a piece of india-rubber or other elastic material, which the child will naturally bite and thus cause the gum to yield before the rising tooth. But, not unfrequently, the dental source of irritation seriously disturbs the general health, and even provokes convulsions. Lancing the gums, relieves both their inflammation and resistance to teething.

*Mal-Eruption of the wisdom-teeth.*—The restricted space afforded to the wisdom-teeth, owing to their position at the back of either jaw, the shape also of the lower jaw curving upwards and the reflection of the gum upwards to the cheek and fauces; are anatomical conditions liable to prevent the easy eruption of these teeth, and pervert the direction of their growth. Hence, difficult cutting and misplacement, particularly in the lower jaw. The upper wisdom-teeth are misplaced backwards or outwards, commonly in the latter direction; the lower teeth point horizontally forwards, sometimes with an inward inclination, and very rarely the direction is outwards. Pain is experienced, especially in moving the jaws and bringing them together; inflammation and swelling succeed, extending to the cheek and fauces so as to render deglutition difficult and simulate ordinary sore-throat. Abscess and ulceration of the gum frequently follow, matter sometimes bursting through the cheek; and painful cutting of a lower wisdom-tooth often occasions a tonic spasmodic contraction of the masseter muscle, thereby closing and fixing the jaws.

The rectification of these tooth-cutting difficulties, pertains rather to mechanical dentistry; but it is necessary that the general Surgeon should be able to recognise the nature of any such case which may come under his notice in the course of his practice.

*Irregularities of the Permanent Teeth.*—These conditions should also be referred to the special experience of the Dental Surgeon.

**DISEASES.**—*Caries and Necrosis.*—The former term is synonymous with the decay of a tooth; a process of disintegration proceeding from some point on the external surface of the tooth, and spreading through the enamel, or the crusta petrosa below the gum, and the ivory; until it penetrates and exposes the interior of the pulp cavity. The opening may be large, involving a large extent of the tooth; or small, as a pin-hole aperture. Discoloration, with the destruction of tooth-substance, will be more or less visible; but exposure of the pulp-cavity always induces fits of *toothache*.

Dental caries may result from some originally imperfect formation of the tooth-structure; more often, it is a consequence of scrofula, syphilis, or the abuse of mercury. Any hereditary taint of the first-named constitutional diseases, will probably cause early caries of the teeth. Certain medicines, as the preparations of iron, and mineral acids, are said to have a carious effect on the teeth, by contact in the act of swallowing them. Pregnancy also seems to have some influence; though it is difficult to explain in what way the teeth become affected.

*Treatment.*—The Surgeon will be called upon to reduce the inflammation and relieve the toothache, consequent on dental caries. The ordinary antiphlogistic measures—fomentations, leeches, aperients, &c., are of little avail, if any, unless the exposed nerve can be deadened, and the pulp-cavity closed. The tooth should be stopped with a small plug of cotton wool, soaked in mastic with chloroform, opium, or other anodyne. Sometimes, stimulant or astringent applications answer better—*e.g.*, creosote, and other essential oils, a bit of pellitory chewed, or a strong solution of nitrate of silver; a solution of tannin or alum. Acidity of the saliva can be neutralized by washing the mouth out with a solution of carbonate of soda or other alkali. Exposure to cold, and of the teeth to hot or cold liquids, sweet, acid, or stimulating food, must of course be avoided; and during an attack of toothache, the pain will mostly impose sufficient personal restraint. Afterwards—when pain and inflammation have subsided—permanent stopping of the tooth, or extraction, should be left to the judgment and skill of the dentist. Any constitutional treatment necessary in regard to scrofula or syphilis, must be conducted on ordinary principles.

*Polypus of the tooth-pulp.*—A dense, gristly, pink-coloured growth of the tooth-pulp, occurs sometimes in a carious tooth; occupying the carious cavity, or presenting a more exuberant growth, it then resembles epulis or a gum polypus. The remains of the decayed tooth will determine the diagnosis. This polypoid growth is very callous and insensitive to pain, and thus differs from the *sensitive growth* of the pulp after fracture of a tooth.

Extraction of the tooth is the only certain and permanent remedy, in either case.

A turgid state of the gum connected with a decayed tooth, gives rise to a wearing pain or *gum-ache*, which becomes excruciating on the accidental contact of a bit of crust of bread or other hard portion of food.

Relief is obtained by freely scarifying or deeply incising the swollen gum; and when the engorged vessels are well unloaded, gargling with a solution of tannin, or other astringent.

*Inflammation of the pulp-cavity*, without caries.—This circumscribed inflammation occasions intense pain which extends deeply beyond the tooth into the jaw, and accompanied with some tenderness of the surrounding gum. Suppuration within the cavity evokes greater agony, the matter being pent up; alveolar abscess probably follows, and partial absorption of the fang or fangs. The tooth is destroyed, even more entirely than by caries; and the partial removal of the tooth would seem to be Nature's mode of ejecting it, as a foreign body.

*Treatment* consists in local and general antiphlogistic measures, and extraction of the offending tooth.

*Neuralgic toothache* should not be mistaken for toothache of an inflammatory character, whether consequent on caries or occasioned by inflam-

mation, affecting the pulp-cavity. The tooth may be apparently sound as it is in the last described form of inflammation; but the pain, grinding, boring, darting, is even more distracting, and it is distinctly paroxysmal—coming and going almost suddenly, at intervals. Similar pains may also occur in other parts, usually subject to neuralgic affections, as supra-orbital-neuralgia; and the cessation of one such affection will perhaps be succeeded by toothache; thus more clearly indicating its neuralgic character.

Malaria, and the rheumatic diathesis, are predisposing causes; and pregnancy seems especially to provoke these attacks, during the earlier months of this state.

The *treatment* relates solely to medicinal measures. Quinine in large doses commonly affords relief; especially when taken shortly *before* an attack, which may thus be averted. Careful regulation of the digestive organs, by antacids, rhubarb and blue pill, will often prove curative where the anti-periodic tonic treatment would fail. A rheumatic tendency must be overcome by medicines suitable to this constitutional condition.

Extraction of the tooth, if structurally sound, would of course be an unscientific proceeding to relieve an affection, however painful, which arises from any constitutional cause. The removal of a tooth temporarily affected, not unfrequently simply transfers the neuralgic pain to another tooth; and in pregnancy especially, it should be the last resource for the relief of a passing symptom.

*Hæmorrhage after Tooth Extraction.*—Protracted and obstinate bleeding sometimes occurs after the extraction of a tooth; the blood continuing to well-up in the socket, until in the course of many hours or days of such hæmorrhage, the patient may be reduced to a state of bloodless exhaustion.

The *treatment* is primarily topical. The socket must be carefully plugged with a strip of lint, the end of which is introduced and driven well home to the bottom, and the strip folded and compressed in successive portions, so as to fully occupy the socket up to the level of the gum or to meet the opposite tooth; the jaws are then to be firmly closed and secured by a broad vertical bandage, passing under the chin and over the top of the head. Astringents have been used with advantage, in conjunction with this plug; it may be dipped in turpentine, or an alcoholic saturated solution of tannin, or loaded with powdered matco leaf. No form of simple plug fits so exactly to the socket as the tooth itself, when it can be obtained. The hæmorrhagic tendency will be advantageously combated by the administration of internal astringents; of which tannin and turpentine have been employed most successfully, and the latter combined with iron, especially the muriated tincture. An elevated posture and derivative warmth to the lower extremities, have some co-operative efficacy. Opiates may become necessary to allay the irritability of sanguineous exhaustion. In women the hæmorrhage may be vicarious to suppressed menstruation; when remedies should be directed to the restoration of this function.

*Tooth-stopping and Extraction.*—These procedures, the adaptation of mouth-pieces, and the construction and fitting of Artificial Teeth, obviously pertain to Mechanical Dentistry.

## CHAPTER XLIV.

## DISEASES OF THE JAWS.

INJURIES.—See Fractures and Dislocations.

FISSURE OF THE PALATE OR CLEFT PALATE.—This congenital malformation consists of a mesial fissure of the uvula alone, or of it and the

FIG. 350.

soft palate; extending sometimes along the hard palate; and occasionally forwards to the upper lip, thus presenting the concomitant condition of single or double hare-lip. Rarely, the lip and the hard palate are fissured, without involving the soft palate. On opening the mouth, this fissured condition is at once seen (Fig. 350), and its obvious interference with speech and deglutition are readily elicited; the patient speaking with a snuffling nasal tone of voice, and in the act of swallowing fluids, some of the fluid regurgitates and may escape through the nose.

*Age for Operation*, to reunite the palate.—Cleft palate when extensive may affect the safety of the infant's life, by preventing a due supply of nourishment; on the other hand, it is ab-

solutely necessary that the patient should have the discretion and the will requisite to remain steady during an operative proceeding of nice manipulation and protracted character, and which afterwards requires an abstinence from speech and restricted deglutition for some days, not to disturb the process of adhesive union. Duly weighing these two considerations, it may be taken as a rule that the child should have reached the age of about fifteen years, before the operation is attempted. Fergusson and Sédillot have, however, performed it on young children with entirely successful results; and in one case, Billroth succeeded before the age of twelve months, in closing a cleft which extended from the lip to the uvula. The state of the general health should of course be considered, with regard to the probability of union after operation.

*Staphyloraphy*—as the operation is often termed—was introduced by Roux; previous to which an artificial palate or obturator had been used. Roux's operation consisted simply in paring the edges of the fissure and bringing them together for union by interrupted sutures, in the manner of hare-lip. It was practised, with modifications by Graef, Warren, Dieffenbach, Liston, and other Surgeons.

Sir W. Fergusson's operation is an essential and most important modification of this proceeding. It consists in first dividing the muscles (Fig. 351), principally the levatores-palati and palato-pharyngei, which as causing traction and motion of the palate, are antagonistic to union; thus introducing the physiological principle of *myotomy* into the operation. Prior to this innovation the flaps of the palate had been brought into

easy apposition, on the mechanical principle of enlarging the palate, chiefly by a longitudinal incision on either side; and Mason Warren also had divided the anterior pillar of the fauces and its attachments to the posterior pillar—an approach to Fergusson's Operation in its performance, but having a purely mechanical design.

Sir W. Fergusson's operation is as follows:—Previous to paring the edges of the cleft, a knife—which he devised, in the form of a spear-head, and curved on a slender stem—(Fig. 352) is introduced into the mouth and passed through the fissure, so that its point shall be laid on the tissues immediately above the velum, midway between its attachment to the bones and the posterior margin, and about half way between the velum and the lower end of the Eustachian tube; the point is then thrust deep, and carried half an inch or more backwards and forwards so as to cut the levator palati across: next the uvula is seized with a pair of long hook-beaked forceps and drawn forwards, thereby putting the posterior pillar of the fauces on the stretch, which is then snipped across with long, curved, blunt-pointed scissors, about half an inch behind the tonsil, dividing the principal part of the palato-pharyngeus; then if it seems desirable, the anterior pillar of the fauces is touched with the scissors, dividing the palato-glossus—a proceeding scarcely requisite. The flaps of the soft palate thus having been relieved from muscular action, they approximate and hang loosely. The remainder of the operation consists in paring the edges of the fissure, and the introduction of sutures to retain them in easy and even contact. The Surgeon seizes the point of the uvula on one side of the fissure with the forceps, drawing it slightly forwards, and then carries a narrow probe-pointed bistoury from the posterior border of the velum to the anterior part of the fissure in the soft palate, so as to make a clean cut raw surface of its margin; the other margin is then pared in like manner. Or, if apparently more convenient, the edges can be pared by seizing the margin about the *middle* of the fissure and holding it firmly, while a narrow, sharp-pointed bistoury or tenotomy-knife is pushed through and run backwards and forward along the margin, thus cutting off a thin slice. The

FIG. 352.

\* Posterior nares and upper surface of the soft palate.—*a*, levator palati; the dark line, shows the place for division. *b*, inner bundle of fibres of palato-pharyngeus, forming the posterior pillar of the fauces; the black line indicates the place for division. *c*, palato-glossus, with the mark for incision, if necessary. The tonsil lies between these two muscles. *d*, tensor palati, the cartilaginous extremity of the Eustachian tube is in front of this letter. *e*, posterior extremity of the inferior turbinate bone. *f*, the septum. *gg*, uvula on each side stretched apart. (Fergusson.)

introduction of sutures is best accomplished by the manœuvre attributed to Mr. Avery. A peculiar curved needle set in a handle, and armed with a smooth thread of the ordinary size for interrupted suture, is passed from below upwards about a quarter of an inch from the cut margin of the fissure, the thread is seized with forceps and drawn

FIG. 353.

as a double thread out of the mouth, with the single ends also hanging out; when the needle is withdrawn. A similar double thread is then passed from below upwards, through the other margin at the same distance from the cut surface and exactly opposite. Thus there is a double thread through each side of the fissure. One thread—the last passed—is now pulled out into a single thread, and the end which hangs through the fissure is passed through the loop of the other thread; when, by pulling the ends of this double thread, the single one is drawn through doubly; the traction thread is then withdrawn, leaving the other with both ends hanging out of the mouth. Two, three, or four threads are introduced in like manner; and then each is tied successively in a double knot reef (Fig. 353), but not too tightly, so as to secure the cut margins in even and easy contact. Sometimes, with all due precaution, a little puckered hole will remain at the junction

of the velum with the hard palate. It is, in my experience, better to leave this aperture than attempt to close it by another suture. In one such case, acting on the injudicious advice of a bystanding friend, the passage of an extra suture broke up the adjoining one, and spoilt the operation.

During these proceedings every manipulation affecting the palate should be clearly *seen*, whether as to dividing the muscles, paring the fissure, or passing and tying the sutures. Any step clumsily taken can scarcely be recovered, on a part hardly large enough to admit of any repetition. Hæmorrhage should be arrested, as may be required, by gargling with ice-water.

After the operation, the patient must neither talk nor eat solid food; although with the freedom of the velum from traction, as accomplished by Sir W. Fergusson's operation, a liberal amount of liquid nourishment may be allowed. The sutures may be left for six, eight, or ten days, and with seeming advantage; when removed, they must be carefully snipped and withdrawn through the newly adherent palate.

The results of this operation in the hands of Sir W. Fergusson have been most satisfactory; of fifty-five cases, all have been successful, but two, and they were exceptional cases. Mr. Avery, Mr. Quain, Mr. Gay, Mr. Walton, and other Surgeons, including myself, have practised staphyloraphy on the same principle. Mr. Thomas Smith has invented a highly ingenious gag for keeping the mouth open during the operation.

The operation for closing fissure of the *hard* palate, was introduced by Dr. Warren of Boston. It consists in paring off the fibro-mucous tissue—including the periosteum, as Langenbeck has particularly recommended—from the bones on each side of the fissure, by means of curved knives; and uniting the lateral flaps with sutures. Mr. Avery was very successful in this proceeding, and more recently Mr. Pollock has revived it.

Or, an artificial palate may be constructed, and worn with much advantage. Mr. A. Nasmyth brought forward this mode of treatment in 1845, and Mr. C. H. Stearns, at the same time in America. The palate or obturator is made of various materials,—a gold or ivory plate, caoutchouc, etc. Mr. Sercombe has brought this resource to such perfection, in its adaptation to very extensive clefts, as to render an operation more a matter of choice than of necessity, for the improvement of the voice and performance of deglutition. Obviously, no obturator should be worn continuously, which can obstruct the development of the jaw in childhood, nor cause absorption of the natural bone, and thus enlarge the fissure.

Perforations of the hard palate produced by necrosis, as the result of syphilis or injury, might be remedied by Warren's operation. But, generally, an obturator will more effectually close the aperture.

**DISEASES OF THE JAWS.**—The connexion of the Teeth and Gums with the Jaws renders it convenient to consider the Diseases of these parts *seriatim*.

**TEETH.**—*Inflammation* and *Abscess*, have been already sufficiently noticed under *Alveolar Abscess*.

**Necrosis.**—The Jaws are subject to Necrosis from at least three causes; Syphilis, Exanthematous poison, especially that of scarlet fever, and Phosphorus. The latter form of Necrosis occurs among those whose occupation exposes them to the fumes of phosphorus, as in the making of lucifer matches. Dr. Wilks, among British writers, appears to have first drawn attention to this source of necrosis,—in the Guy's Hospital Reports of 1846-47. In Germany, phosphorus-necrosis was recognised as early as 1839, by Lorinser, who published a paper upon the subject in 1845; and was followed by other authors.

The mode in which the necrosis is produced, seems to be by the entrance of phosphorus-fumes into the osseous structure of the jaws, through carious teeth or an open socket; the disease never arising when the teeth of the operatives are sound. The liability of the two jaws to this necrosis appears to be about equal, or with a slight preponderance against the lower jaw. Of 52 cases given by German authorities, 21 were of the upper jaw, 25 of the lower jaw; in 5 both jaws were affected, and 1 case is uncertain. The English statistics gathered by Mr. Salter point to nearly the same conclusions. Excellent specimens of the disease as affecting both jaws, are to be found in the Museum of St. Bartholomew's Hospital.

**Symptoms.**—The same symptoms arise, whatever be the cause of Necrosis; but in that proceeding from phosphorus, they are most marked. Toothache, intermittent at first, becomes continuous; the teeth loosen and pus exudes from the sockets. The gums are swollen and tender, and detached more or less from the alveoli. Swelling of the face takes place, to perhaps a considerable extent, so that if only one side of the jaw is affected, a peculiar lop-sided appearance results; one or more fistulous openings also discharge pus and lead down to bare and dead bone. The general health yields under the constant suffering, loss of food, and the poisonous influence of purulent matter swallowed daily.

**Terminations.**—Death may, at length, take place from exhaustion, or rapidly from gangrene of the cheeks and lips; recovery occasionally ensues, with considerable loss of bone and deformity. Repair after necrosis of the jaw is sometimes very complete, the formation of new bone being very prolific. A pumice-stone deposit of bone on the sequestrum is

almost constant, and has been regarded as characteristic of phosphorus-necrosis; but this, Mr. Christopher Heath affirms, is not necessarily connected with phosphorus. It is derived from the periosteum, and though resembling true bone, it is decidedly of lower development. This deposit is not found in the disease of the upper jaw. It would seem also not to be peculiar to phosphorus-necrosis, the pumice-like bone sometimes encrusting a sequestrum, which has resulted apparently from rheumatic periostitis; as shown by Mr. Perry's case in the *Medico-Chirurgical Transactions*, Vol. xxi. In a remarkable case recorded by Mr. Thomas Smith, in the *St. Bartholomew's Hospital Reports* of 1865, phosphorus-necrosis of the entire lower jaw was followed by restoration of the jaw. The new bone appears to be produced either from the periosteum, or from the surrounding soft parts when the periosteal membrane has lost its vitality; and in Mr. Smith's case, the reparation thence derived was sufficient to reproduce the jaw. In that case also, two other notable points were illustrated; the reparative material was formed not around, but entirely in front of or below the sequestrum, and there was an absence of pumice-stone deposit. The former condition, as pertaining to reparation, existed in the lower jaw of a patient, some years since, at the Royal Free Hospital; and from whom Mr. T. Wakley removed the sequestrum, which extended nearly from angle to angle of the jaw. I assisted in the operation, and particularly noted the form of reparation. Repair of the lower jaw seems to be but temporary; the new bone diminishing by absorption to a mere arch, and ultimately being scarcely sufficient to keep out the lower lip, the chin is quite lost. It is a question, how far this loss by absorption might be prevented by supplying the new jaw with a function through the means of artificial teeth?

*Treatment.*—The cause of necrosis must, of course, be removed; any exposure to the influence of phosphorus would perpetuate that form of the disease. Any decayed teeth or stumps should therefore be extracted, as the source of local irritation. Detergent gargles of chlorinated soda or permanganate of potash may be advantageously used to cleanse the mouth. Opium to allay pain, with tonics and whatever nutritious food can be taken to support the strength, are the only measures available pending the detachment of the sequestrum, and the production of an enveloping shell of new bone adequate to maintain the form of the jaw. The sequestrum is then to be extracted through the mouth, if possible, or through incisions placed so as to leave the least subsequent deformity. The permanent set of teeth should be preserved, when practicable. "Subperiosteal resection" has been much advocated by foreign Surgeons; as M. Rizzoli, Flourens, Maissonneuve, and Ollier of Lyons. This operation does not apparently differ from the extraction of sequestra, as ordinarily practised.

Prevention in the case of phosphorus-necrosis has been ably investigated by Dr. Bristow in Mr. Simon's Report to the Privy Council, 1863. Working with *amorphous* phosphorus is unattended with danger, for the disease arises exclusively from the fumes of common phosphorus.

*UPPER JAW.*—*Abscess of the Antrum.*—Arising from the irritation of carious teeth, which may be in immediate relation to the antrum, or unconnected with that cavity, as the incisor teeth; the disease commences as alveolar abscess, which bursts, directly or indirectly, into the antrum. But, abscess of the antrum may result from catarrhal or other inflammation of the lining membrane; or it may be of traumatic origin,—the

extraction of a tooth communicating with the cavity, the entrance of a foreign body, a blow on the cheek, or injury received during birth in a pubic presentation. An instance of the latter occasion of injury, having induced abscess of the antrum in an infant a fortnight old, is recorded by Dr. G. A. Rees in the *Medical Gazette* (N. S.), vol. iv.

The *symptoms* are, at first, those simply of inflammation of the lining membrane; dull, deep-seated pain shooting up the face and to the forehead, swelling and tenderness of the cheek, with considerable fever and constitutional disturbance. A slight rigor, sometimes, announces the formation of matter, which may find its way into the nostril, when the patient is lying on his sound side, either through the normal opening, or an opening resulting from absorption, as maintained by M. Giralès. Generally, the pus not finding a ready exit, distends the antrum; bulging out the cheek, uplifting the floor of the orbit, depressing the hard palate, and loosening the teeth, obstructing the nasal duct and closing the nostril. The wall of the cavity undergoes absorption, and becoming thinned, it yields a peculiar parchment-like crackling under pressure with the finger. The matter may burst externally, into the mouth, or into the nostril; in either case considerable necrosis and scar will probably be the result.

*Treatment.*—Any carious teeth or stumps must be extracted. This may be followed by a flow of pus, when the introduction of a trocar through the alveolus will completely evacuate the matter. When all the teeth are apparently sound; the first molar tooth should be extracted—as having the deepest socket and being most liable to decay, and then the socket must be punctured.

*Puncturing the Antrum.*—Care should be taken in using the trocar, lest it penetrate with a jerk and injure the orbital plate. The alveolus may be punctured above the gum, and this will be necessary in the rare case of suppuration occurring in old people, after loss of the teeth. The cavity should then be cleansed by syringing with warm water, by means of a curved canula and hydrocele elastic bottle. A slightly astringent injection may be advisable; and a weak solution of permanganate of potash or sulphate of zinc, answers admirably. The admission of any particles of food should be prevented, by plugging the aperture with cotton-wool; or, as Mr. Salter has suggested, by fitting a metal plate to the mouth with a small tube to fill the aperture, which can be corked at pleasure and serves as a pipe for injection. In puncturing the antrum, the possible subdivision of this cavity, owing to the existence of bony septa, will be an obviously important condition; and especially with reference to the extraction of a foreign body, as the fang of a tooth lodging in one of these subdivisions.

*Chronic abscess of the antrum*, producing a slow expansion of this cavity, may be mistaken for a solid growth, as Liston has seen happen; and particularly when there is considerable hypertrophy of the osseous wall in consequence of prolonged irritation, a condition which Stanley mentions as having occurred in the practice of Sir W. Lawrence.

*Dropsy of the Antrum.*—The symptoms are the same as those of abscess, only that the enlargement is painless, and more slowly produced. The fluid evacuated is a clear or yellowish serous fluid, and frequently contains flakes of cholesterine. This condition was formerly attributed to obstruction of the aperture between the antrum and nostril; thus allowing a gradual accumulation of the mucous secretion. It is now regarded as the production of a cyst or cysts within the antrum, or in connexion with

the fangs of the teeth,—dentigerous cysts, which either grow to such a size as to be mistaken for the cavity of the antrum when opened, or burst into the antrum leaving no trace of cyst-formation. Hence the character of the contained fluid, serous and not mucous.

The swelling of the cheek may subside, the jaw resuming its original size; and the discharge from a punctured alveolus ceasing, the aperture closes. Collapse of the antrum may occur, with absorption of the front wall causing a projection of the upper wall, in the form of a prominent horizontal ridge of bone immediately below the orbit. This remarkable deformity was found in the person of an old woman, a subject in the dissecting-room at King's College; and it was originally described by Sir W. Fergusson as probably an unique specimen.

Dropsy, like abscess, of the antrum, may be mistaken for a solid growth; and Mr. Heath notices a case in which a very able Surgeon removed the upper jaw before discovering the error of his diagnosis. An exploratory puncture will determine the question; as was shown in a very remarkable case of simulation which occurred in the practice of Sir W. Fergusson, and is recorded in the Medical Times, 1850.

Puncture of the antrum and evacuation of the fluid, is the only mode of cure; and this proved successful in the case last cited.

TUMOURS.—*Hyperostosis* or simple osseous hypertrophy, and various morbid growths or tumours, are liable to form in, or in connexion with, the Jaws, as in other parts. Thus, *fibro-cellular*, *fibrous* and *recurrent fibroid*, *cystic*, *cartilaginous*, *osseous* and *myeloid*, *vascular*, or *erectile*, and *cancerous* tumours may severally occur.

The pathology of all these morbid growths differs in no essential particulars from that of the same growths in other situations.

Their *diagnosis* demands some special notice. The differential characters of these tumours are, however, not well marked, and their diagnosis, there-

fore, is by no means unequivocal; but this difficulty is practically unimportant, excepting with reference to the distinction of cancerous or malignant and non-malignant forms of maxillary growths.

In examining any tumour of the *Upper Jaw*, a careful inspection and palpation, as far as possible, should be made of the face, mouth and nares. In making a rhinoscopic examination, the nares may be illuminated by the Laryngoscope. A small mirror is placed at the back of the throat, at such an angle that luminous rays falling on it are reflected into the nares, whilst the image formed in the mirror is seen by the observer. An antral tumour can thus be clearly distin-

FIG. 354.

guished from a polypus springing from the turbinate bones, or a growth springing from the base of the skull. The condition of the hard and soft palate should be examined with the finger, and behind the soft palate to ascertain any extension of the growth in that direction. The consistency of the projection beneath the teeth is more readily discovered, and the finger should be passed over it both outside and inside the cheek.

*Non-malignant* growths are more or less hard to the touch, and painless. They grow slowly, and have no tendency to involve surrounding parts or the skin, except by mechanical interference; the general health also remains unaffected. (Fig. 354.)

This represents a *fibrous* tumour, removed by Liston, and with a permanently successful result. Myeloid and vascular tumours are softer than other non-malignant growths, and more vascular in appearance where they are covered only by mucous membrane. They grow more rapidly, occasionally ulcerate, but do not fungate, as in fibrous tumours of the upper jaw, and may then bleed profusely. *Encephaloid cancer* is characterized by its softness, and gnawing pain affecting the face and head; its rapid growth, and tendency to fungate and bleed.

Tumours of the *Lower Jaw* are more open to diagnosis. *Non-malignant* growths are characterized by hardness and slowness of growth, with no tendency to fungate within the mouth and no enlargement of the neighbouring lymphatic glands. After a time, the unchecked growth may burst through the skin and present a fungating mass; but this has a more healthy appearance and is of slower growth than the encephaloid fungus. (Fig. 355 and Fig. 356.)

The former, was a case under the care of Sir W. Fergusson; operation was deemed unadvisable, owing to the exhausted state of the patient, and death ensued. The latter figure

FIG. 355.

FIG. 356.

represents a *fibro-cellular* tumour of monstrous size, in Mr. Heath's celebrated case; it was successfully removed, but death took place on the sixth day, from exhaustion. *Cancerous* tumours generally originate within the bone, and grow rapidly; tumours having these characters are almost invariably cancerous.

TREATMENT. — *Medicinal* treatment with the view of inducing absorption can be of little avail. A small enchondroma of the upper jaw is said to have been thus removed, under the care of Mr. Stanley, by the application of iodine.

Early and complete *excision* of the growth is the only cure; in non-malignant tumours, before the anatomical relations of the growth have become too complicated to admit of complete extirpation; in cancerous tumours, before the surrounding structures have become involved.

The results of such operations are more successful in respect to tumours of the lower jaw, as the whole disease can be more completely removed. What security there may be in the removal of half the jaw affected with cancer, is still an open question.

EXCISION OF THE UPPER JAW.—Of several methods of operation, that which is most generally applicable, is as follows:—The patient sitting, or lying recumbent and under the influence of chloroform, the central incisor tooth of the diseased jaw is extracted, and two incisions are then made. First, a bistoury is entered at the junction of the malar and upper maxillary bones, and carried down with a curvilinear incision into the angle of the mouth. Secondly, another incision is made from the nasal process of the upper maxilla down along the side of the nose, round the ala, which it detaches, and perpendicularly through the centre of the upper lip into the mouth. (Fig. 357.) The flap, thus defined, is dissected up to the

FIG. 357.

FIG. 358.

margin of the orbit, and its contents—the eyeball and its surroundings, cautiously raised from the floor of this cavity, protected by a curved spatula held by an assistant standing behind over the head of the patient. The bones are then divided by strong cutting-pliers (Fig. 358); the

junction of the malar bone first, then the nasal process, one blade of the pliers being inserted into the orbit—the eye still protected, and the other into the nose; and lastly, the alveolus is notched with a narrow-bladed saw, where the incisor tooth was extracted, and the palatine arch divided by passing strong, sharp-cutting, pliers (Fig. 359)—one blade into the mouth and the other into the floor of the nose. The palatine process of the palatine bone with the velum palati, or soft palate, should be left untouched, if possible. The osseous mass thus detached from its connexions, is drawn downwards and forwards, and easily removed. Ligatures must be applied to the facial and transverse facial arteries, or any other vessels which cannot be secured by torsion or pressure. The large cavity exposed is plugged with lint from the bottom, the flap of integument replaced over it, and retained in position by a few twisted sutures in the cheek and upper lip. No portion of integument should be pared off, however redundant it may at first appear; having been stretched over the osseous tumour, it will contract and pucker up. The ultimate disfigurement resulting from this operation is comparatively inconspicuous. (Fig. 360.)

FIG. 359.

The malar bone may be involved in the disease, with the whole of the superior maxilla; then the zygoma and junction of the malar with the external angular process of the frontal bone, must be divided externally, with the pliers, and the operation completed as for removal of the superior maxilla alone.

FIG. 360.

The malar bone and the orbital plate of the superior maxilla, forming the floor of the orbit, may be sound; then, a groove having been made with a small saw, across from the nasal process of the maxillary to the outer margin of the malar bone, the separation is completed with the forceps, including the remainder of the bone as above described.

*Modifications of this Operation* have been practised with success by Sir W. Fergusson.

(a) A transverse incision, slightly curved, may be made from the junction of the malar bone below the eye, across to the nasal process (Fig. 361), instead of curving downwards into the angle of the mouth. Considerable hæmorrhage will thus be avoided, and the other incision may be made as already indicated.

(b) A single incision from the angle of the mouth upwards and outwards, has enabled him to remove tumours of some size; or an incision through the centre of the upper lip to the base of the columna and into the nostril, has afforded sufficient space for the removal of tumours of such size as it would be deemed advisable to operate on.

EXCISION OF THE LOWER JAW.—*Partial* removal of this bone will generally suffice—the disease being situated on one side, and between the symphysis and angle of the jaw (Fig. 362), or involving the ramus, or extending beyond the symphysis to the other side.

FIG. 361.

*Complete* removal of the jaw, by disarticulation at the temporo-maxillary articulation, on either side, is rarely rendered necessary by the extent of the disease.

The plan of any such operation, partial or entire, is the same. The object is, to remove the diseased bone, with the most facility and least ultimate deformity. An incision under the chin, along the body of the bone and ramus, answers both purposes.

(1) *Partial excision*—say of one-half of the jaw, is performed as follows:—The point of a scalpel should be entered behind the articulation, and an incision carried down the posterior border of

the ramus behind the angle,

FIG. 362.

thence along under the body of the bone to the chin, and curving upwards, it terminates about an inch from the margin of the lip. In the

course of this incision, the facial artery will be divided, but the coronary is avoided. The former is at once ligatured. The flap is dissected up, thoroughly exposing the tumour, the knife passed under it into the cavity of the mouth and along the jaw, keeping close to the bone, and thus detaching the mucous membrane. The central incisor tooth of the diseased side having been extracted in commencing the operation, the jaw should here be notched with a small saw, having a moveable back (Fig. 363), and clipped through with cutting-forceps by a firm and snapping grip. Laying hold of the tumour with one hand, and moderately depressing the body of the bone, the Surgeon severs the attachment of the temporal muscle to the coronoid process by a light touch with the knife; then, the masseter muscle having been already detached in raising the integument, the articulation is entered from the front, and by carrying the knife round the condyle, with its edge closely turned towards the neck of this process to avoid wounding the internal maxillary artery, the pterygoid muscles are divided, and the excision completed. (Fig. 364.) This figure represents the half of the jaw, as a cystic tumour, removed by Sir W. Fergusson, from the patient in Fig. 362. Should the internal maxillary require ligature, the common trunk of this vessel and the temporal artery—the termination of the external carotid, will be found as it emerges from under the border of the posterior belly of the digastric muscle. The cavity is filled with lint, the flap replaced, and neatly retained with twisted suture.

FIG. 363.

A *more partial* excision of the lower jaw—between the symphysis and angle, can be effected in like manner, the incision, under the body of the bone extending only between these two points, and the cutting-forceps being applied posteriorly at the angle, as well as at the symphysis.

FIG. 364.

*Beyond* the symphysis, the operation may be extended by continuing the incision, and applying the saw and forceps at the limit of the disease, on either side. Whenever the operation extends beyond the symphysis, necessitating a division of the muscles on either side, which pass from the jaw to the tongue, this organ must be secured and drawn forwards by means of a ligature previously introduced through the tongue, and thus held by an assistant. Otherwise, the tongue, loosened anteriorly, may be retracted into the pharynx—swallowed, in fact, and threaten, or actually occasion, suffocation.

(2) The *entire* jaw can be removed *en masse*, by an incision carried round, and a disarticulation corresponding to that for the removal of half the bone.

During the process of healing by granulation, the patient must be fed with liquid food, spooned into the mouth or sucked through a tube. A dense, fibrous tissue gradually forms a kind of substitute jaw; and, espe-

cially when the articulations are left untouched, the movements and appearance of the lower part of the face are far more perfect than might be expected. (Fig. 365.) It has often occurred to me, that some kind of

FIG. 365.

the overhanging multitude of students in the theatre—lives in my memory with the freshness of yesterday.

**CLOSURE OF THE JAWS.**—This condition implies more or less inability to open the mouth and to perform the act of mastication. It may be spasmodic or permanent.

(1) *Spasmodic* closure, sometimes of several weeks' duration, is almost invariably connected with difficult eruption of the wisdom-teeth of the lower jaw. Owing to want of space for, or mal-position of, the tooth, constant pressure thus occasioned, induces a state of tonic spasm of the masseter and internal pterygoid muscles.

The *treatment* consists in opening the mouth under the influence of chloroform, and with the aid of wedges or a screw gag; the second molar must then be extracted to make room for the wisdom-tooth, or the tooth itself may be removed.

(2) *Permanent* closure may be the result of several causes operating mechanically—profuse salivation, with sloughing of the cheeks and the formation of rigid cicatrices which draw up and hold the lower jaw closely and tightly against the upper—ankylosis of the temporo-maxillary articulations, in consequence of injury, or of arthritic inflammation; the formation of an osseous bridge between the jaws or the lower jaw and temporal bone, as a rare consequence of chronic articular arthritis—pressure of a neighbouring tumour, especially in the parotid region, so as to directly fix the joint. Besides interfering with mastication and articulation, permanent closure in early life is often followed by stunted development of the jaw, presenting a marked shortening of the chin and an oblique direction of the front teeth. With perforation of the cheek, there is a constant dribbling escape of the saliva, and the most disgusting disfigurement.

artificial supplementary jaw, with teeth, might be fixed upon the fibrous matrix, and when an appropriate opportunity occurs, I shall endeavour to put this notion into practice. My earliest recollections of these operations on the jaws date back to their memorable performance by Mr. Liston, at the University College Hospital; and, although nine-and-twenty years have elapsed since first I witnessed such an operation, the scene—ere the days of chloroform or ether—of the master operator, with his massive hand, snapping through the jaw-bone of the patient seated before him, the group of assistants, and

*Treatment* must have reference to the nature and situation of the cause of closure.

Rigid cicatrices may be relieved, not perhaps permanently remedied, by excision of the contracted integument; the patient wearing for months or years, the silver shields adapted to the upper and lower jaws by Mr. Clendon, or other suitable apparatus, to counteract the tendency to re-contraction. Ankylosis of the temporo-maxillary articulations may be overcome by mechanically breaking up the adhesions, under the influence of chloroform. An osseous bridge, connecting the jaws, can be severed and removed by cutting-pliers and a small saw; but this proceeding must be warranted by an accurate diagnosis. Any tumour which mechanically impedes the motion of the jaw may be extirpated, provided its anatomical relations to the parotid gland do not contra-indicate such operation.

The formation of an *artificial joint* in the lower jaw was originally suggested by Esmarch in 1855; followed by Rizzoli in 1857, who quite independently conceived a similar idea. The one, however, performed excision of the joint; the other simply cut through the jaw, without removing any portion of bone.

Esmarch's operation appears to be preferable, as facilitating the formation of a false, moveable joint. It was first performed by Dr. Wilms of Berlin, in 1858, and successfully; shortly afterwards by Esmarch, with equal success; and subsequently by Diltz of Vienna, and by Wagner of Königsberg. It was introduced into this country by Mr. Mitchell Henry, the patient sinking from pyæmia; a few weeks afterwards Mr. Christopher Heath performed the operation, and in two cases with the most satisfactory results. A small incision along the edge of the jaw exposes the articulation, when sufficient bone should be removed to give free motion, say half an inch, by means of a Hey's saw or the chain-saw.

Rizzoli's operation has proved successful in his own hands, in four cases, and it has been performed also by Professor Esterle. No external incision is made, but section of the jaw—not excision—is accomplished from the interior of the mouth, with powerful forceps. Both these operations have proved unsuccessful, owing to reunion of the divided jaw.

---

## THE NECK.

---

### CHAPTER XLV.

#### INJURIES OF LARYNX AND TRACHEA, PHARYNX AND ŒSOPHAGUS.

**LARYNX and TRACHEA.—WOUNDS OF THE THROAT.**—These injuries are inflicted commonly with suicidal intent, and usually therefore with a cutting instrument, as a razor or knife; forming the wound ordinarily known as cut-throat. This wound is a transverse and upturned incision, somewhat jagged or lacerated, and varying in depth and extent.

It may be a *superficial* wound, dividing only the integument, and to a limited extent, in front of the throat; or extend across the throat, from side to side, or ear to ear, and sever the carotid vessels—artery and vein, with perhaps the pneumogastric nerve—on one, or both sides, and if sufficiently low down in the neck, the phrenic nerve may be touched. An

integumental wound commencing on one side of the throat, may divide these vascular and nerve-trunks, on that side; but a wound sufficiently resolute to extend to the other side—cutting the throat, as it is popularly termed, from ear to ear—and dividing the vessels on both sides, will scarcely be effected without involving deeper parts.

A *deep* wound involves the air-passages, and perhaps the pharynx or œsophagus. The appearances and functional phenomena differ somewhat according to the situation of the wound. It may be *above* the *hyoid* bone; thus opening the mouth under the tongue, which perchance will be touched, and the power of deglutition is lost. Or, the wound may pass across the *thyro-hyoid space*, above the larynx, the commonest situation; opening the *pharynx*, and perhaps shaving off the epiglottis or touching the glottis itself, and here also deglutition is incomplete. Or, the *larynx* may be divided anteriorly, presenting a transverse gap, through which the air issues during each expiration, with a rushing, bubbling sound, and with almost sufficient force to blow out a candle if held near the aperture. The voice is lost or reduced to a broken whisper, but it is restored on closing this opening in the windpipe. Similar phenomena are observed when the *trachea* is opened. The *thyroid body* will be almost necessarily involved, an important source of hæmorrhage. The *œsophagus* can be opened only by a deeper wound, passing through the trachea. But, in rare instances, both the windpipe and gullet have been divided down to, and implicating, the *vertebral column* beneath. The windpipe is usually cut in front and high up, the suicide imagining that a wound of the air-passage is mortal; and thus the prominence of the larynx mostly invites the attempt. Hence also, the great vessels and nerves, on either side of the throat providentially escape injury.

*Consequences and prognosis.*—*Hæmorrhage* is the immediate source of danger. It may be venous; proceeding from the plexus in front of the trachea, or from the internal jugular vein. The carotid trunk or its branches are the source of arterial hæmorrhage; and the trunk must be wounded if the jugular vein be implicated. Death may speedily ensue, directly from hæmorrhage, or from the blood trickling into the windpipe, producing asphyxia, or inflammation of the lungs at a later period. Occasionally death arises from the accidental sucking up of air into the veins, inducing asphyxia. Division of a large nerve, the pneumogastric or phrenic, occurs usually in conjunction with wound of the larger vessels; and division of the phrenic on one side only may be almost immediately fatal, either by partially suspending respiration, or in consequence of inflammatory congestion of the lungs. *Asphyxia*, in connexion with, or as a consequence of cut-throat, may arise, as already stated, from hæmorrhage into the trachea, or from lesion of the phrenic nerve, or congestive pneumonia consequent on either state; but pneumonia or bronchitis is liable to ensue from the introduction of cold air into the lungs through the wound, the inflammation extending downwards from the aperture in the windpipe. *Edema of the glottis* in consequence of inflammation, or irritation or impaction of a partly detached epiglottis, may severally induce asphyxia, when the wound is above the larynx. Loss of the natural sensibility of the glottis, preventing its efficient closure, will allow food to pass into the larynx and through the external wound, without any wound of the pharynx or œsophagus. Accumulation of mucus in the bronchi is also apt to occur, in consequence of their diminished sensibility. *Lastly*, the respiration may be mechanically impeded below the

epiglottis; either by a partly detached portion of cartilage hanging into a laryngeal or tracheal wound, or by overlapping of the lower portion of the trachea by the upper portion, when this tube is completely divided.

*Treatment.*—The general indications are—to arrest hæmorrhage, to adjust the wound for reparation, to obviate any difficulty of respiration, to administer food, and to avert inflammation of the trachea, or lungs.

(1) *Hæmorrhage* must be arrested by the ligature of any bleeding vessel, whether artery or vein, so as to prevent any oozing or trickling into the larynx or trachea. The introduction of a silver tube into the windpipe aperture of the wound will obviate the liability of blood being sucked in by each act of inspiration. This should be withdrawn as soon as oozing hæmorrhage has ceased. (2) The *wound* should be adjusted by position, rather than by sutures. An *integumental* wound may be advantageously united by a few points of suture, throughout its extent. In a *deeper* wound, involving the windpipe, partial union only can take place, owing to the mobility of the parts subject to the actions of respiration and deglutition; the wound closes chiefly by granulation and cicatrization. If primary union happen to occur in the central part of the wound, coagula are apt to accumulate beneath, threatening suffocation, and the wound will have to be reopened for their removal. The extremities, or integumental portion of the incision, may be retained together by a suture or two, leaving the central portion open; the head should then be brought forwards, so as to depress the chin towards the sternum, and fixed in position by a bandage round the crown, with a lateral strip passing down on either side of the face, fastened to a band around the chest. If the trachea be completely divided, a suture or two should be inserted into each side of the *tube*, to retain its ends together. (3) Difficulty of *breathing* must be prevented or overcome, by having regard to the circumstances already enumerated which give rise to dyspnœa. The temperature of the apartment should be maintained at about 80° Fahrenheit; and the air moistened and softened, as it is breathed through the windpipe aperture, by covering the wound with a piece of muslin loosely folded, beneath which a clean sponge moistened with warm water may be placed adjoining the air-aperture. This aperture must be carefully kept open and free of any clot, or other occasion of impediment to the breathing. A wound above the larynx, and followed by œdema of the glottis, will necessitate recourse to tracheotomy. (4) The administration of *food* becomes a difficulty only when the pharynx or œsophagus is opened. Food is best introduced by means of a large-sized elastic catheter, or the tube of the stomach-pump, passed through the mouth into the gullet below the opening. If this mode of feeding cause great irritation, nutritive enemata may be resorted to. The food is necessarily liquid, but strong beef-tea, soup, or Liebig's *liquor carnis*, milk, eggs beat up with brandy or wine, can be thus administered, and the patient's life indefinitely prolonged, until he is able to swallow without assistance.

(5) *Inflammation*, in the form of bronchitis, will probably be averted by due attention, as already directed, to the temperature of the atmosphere which the patient breathes through the windpipe aperture; and pneumonia prevented by watchful observation, more especially with regard to any trickling hæmorrhage into this aperture. In the event of either form of inflammation, the treatment accordingly must be conducted on ordinary principles; taking however into consideration the state of the patient, as reduced by hæmorrhage and his depressed mental condition.

The wound, in the course of granulation, requires nothing more than water-dressing, or other simple applications.

*Aërial Fistula* sometimes ensues; the skin having doubled in and become adherent to the edge of the aperture in the air-tube, a jet of air passes and repasses through, with each act of respiration. This happens most frequently in the thyro-hyoid space. Mr. Erichsen has found the following operation successful in closing such a fistula. The edges of the opening are to be freely pared, and the knife passed under them for some distance to detach them from the subjacent parts, a vertical incision also being made through the lower lip of the opening, splitting it downwards. Two points of suture are then inserted into each side of the horizontal incisions, bringing their edges into contact; but the vertical cut is left free for discharges and mucus to drain away, and for the expired air to escape, lest emphysema occur. Unless this outlet be left, the sutures will burst, and union of the edges be frustrated. An aërial fistula cannot be safely closed when the larynx above is obstructed, and it may even become necessary to enlarge the opening and introduce a silver tube to compensate for the laryngeal obstruction.

FOREIGN BODIES IN THE AIR-PASSAGES—*Larynx, Trachea, or Bronchi*.—Various substances that admit of being swallowed, occasionally pass into the rima glottidis, and thence, perhaps, lower down into the air-passages; any such body is, however, not swallowed into the glottis, in an effort of deglutition, but *inhaled* into this opening from the mouth, by a sudden inspiration, in the act of laughing or talking with the substance in the mouth. It is drawn by the current of air between the dilated lips of the glottis. Various substances may thus pass the “wrong way”—a bit of meat, a cherry-stone, a bean, pea, nut-shell, or a tooth, money, a button, a bullet, pill, or pebble, a pin, fish-bone, or piece of stick.

The *Symptoms* are those of suddenly-obstructed respiration, and of irritation, followed by those of inflammation. But the symptoms vary in intensity according to the situation of the foreign body.

Impacted in the *rima glottidis*, any substance so placed completely obstructs respiration, and the individual, suddenly turning blue in the face, drops down dead almost instantaneously. Not uncommonly a violent explosive cough or two ejects the foreign body, and the peril is over, although spasmodic coughing still remains for a time, owing to the irritation. In the *larynx*, the foreign body may lodge or hitch in one of the ventricles, or slip down into the *trachea*; the same spasmodic coughing is evoked, with great difficulty of breathing and sense of suffocation, and pain referred to the episternal notch, a croupy sound is heard through the stethoscope, during respiration, but the voice is broken or lost. All these symptoms are most intense when the larynx is the seat of impaction; in the trachea, the foreign body has more room, and the urgent symptoms may subside for a while; or the foreign substance moving up and down occasionally, particularly if the patient move, coughing returns with increased violence, and the body may be heard and even felt to strike the larynx, seeming to threaten instant suffocation. In the *bronchi*, a foreign body is comparatively tolerated; the respiration is more or less embarrassed, and a whistling or murmuring sound may be heard over the seat of lodgment; sometimes also, during coughing, the body is dislodged and driven upwards. The right bronchus is generally that into which the foreign body falls; it being more directly in the middle line.

The *diagnosis* from laryngitis or croup, turns mainly on the history of

the dyspnœa; the apparent introduction of a foreign body, in the act of eating and laughing, for example, and the sudden origin of the symptoms from that occasion, constitute the chief points of distinction.

*Consequences.*—Inflammation of the larynx, trachea, bronchi, or lungs, supervenes in a variable period; a few days, or an indefinite time elapsing after the more urgent symptoms of dyspnœa have subsided. Cough, pain, and muco-purulent, perhaps bloody, expectoration, succeed; and they continue until the patient is worn down in a few months, or a year or two, and dies from hectic exhaustion. Rarely, the foreign body may be coughed up again; in one instance, Heckster relates that a ducat was thus ejected after two years and a half imprisonment; in another case, Tulpus states that a nut-shell was coughed up after a lodgment of seven years; the patients in both cases recovering. Sometimes, death ensues, although the body has been ejected; as in an instance given by Sue, in which a pigeon-bone was spat up seventeen years after its introduction, the patient dying about a year afterwards from marasmus.

The *prognosis* depends on the size and physical character of the foreign body, and the period of its incarceration. Mr. Erichsen finds that, after the immediate danger, the greatest risk occurs between the second day and the end of the first month, no fewer than 11 patients out of 21 having died during this period; but that the mortality diminished until the third month, when it increased again. The cause of death also varies according to the period of the fatal result. During the first twenty-four, or forty-eight hours, it happens from convulsions and sudden asphyxia; during the first few weeks, it is apt to occur from inflammation of the lungs; and after some months have elapsed, death results from hectic exhaustion.

*Treatment.*—The obvious indication is to get the foreign body out of the windpipe; but the proceeding to be taken should be guided by the urgency of dyspnœa. (1) Impaction in the *rima glottidis*, will demand—when opportunity offers—immediate search below the root of the tongue with the finger, and extrication of the substance from the chink of the larynx. Failing to accomplish its removal, laryngotomy must be performed immediately, and a probe passed through the laryngeal aperture into the larynx to dislodge the foreign body. (2) Lodgment within the *larynx*, or *trachea*, may allow of some delay; in order to quiet spasm of the laryngeal muscles which prevents the ejection of a body, not otherwise itself too large to be coughed up. With this view, it may be desirable to bring the patient somewhat under the influence of narcotics, or chloroform. Inversion of the body—by holding the patient with his heels upwards and head downwards, shaking the body at the same time or slapping the back, will probably cause the substance to drop out of the air-passage and escape through the mouth. A child can be readily held, head downwards; but, for a grown person some mechanical contrivance may be necessary, such as was used in the case of the eminent engineer, Mr. Brunel, when he accidentally swallowed a half-sovereign. If suffocation threaten, the attempt must be abandoned.

*Laryngotomy* or *tracheotomy*, should be resorted to without delay, in the event of the foreign body still remaining in the windpipe. The respiration is thus set free, and the irritability of the laryngeal muscles subsides; so that the substance may be expelled through the larynx, or more probably through the artificial aperture. Sometimes, it can be safely extracted, or made to drop out by inversion.

The *results* of cases, as left to nature or subjected to treatment, are well shown by the statistical facts collected by Professor Gross, respecting 159 cases of foreign bodies in the air-passages. Spontaneous expulsion occurred in 57, 8 terminating fatally. Inversion of the body alone was successful in 5 cases, and unsuccessful in 6. In 68 cases, tracheotomy was performed; 60 lived and 8 died. In 17, laryngotomy was practised; 13 lived and 4 died. In 13, laryngo-tracheotomy was performed; and of these, 10 recovered and 3 died. It thus appears, that of the 98 cases in which the windpipe was opened, for the removal of foreign bodies, 83 were successful, and 15 fatal,—or the deaths were in the proportion of 1 to 5½. Of the three kinds of operation, tracheotomy was most favourable, the deaths being only in the ratio of 1 to 8½; whereas after each of the other two operations, the proportion of deaths was twice as great. The most frequent cause of death was inflammation of the lungs.

SCALDS OF THE GLOTTIS, MOUTH, and PHARYNX—not unfrequently occur among the children of the poor, in their attempting to drink from the spout of a kettle, containing boiling water. The act of swallowing is not complete, but the inside of the mouth and pharynx are scalded, and œdema of the glottis is speedily induced; the interior of the larynx remaining unaffected. (Fig. 366.) A similar state may be produced by the inhalation of flame in the explosion of gas or fire-damp.

FIG. 366.

The *symptoms* are, immediate and urgent suffocative cough, and difficulty of breathing; and the appearances are, puffed and turgid lips, the interior of the mouth and fauces having a whitened and soddened aspect. Death soon ensues, unless the inflammation be subdued.

*Treatment*.—Leeches to the throat, and small doses of calomel and opium, may succeed in reducing the œdema; but the urgency of the dyspnœa will probably necessitate tracheotomy without delay, as the only chance of safety; and a tube must be introduced into the tracheal aperture and retained there, until this has subsided under the continuance of remedial measures. The operation is rendered more than usually difficult, by the shortness, fatness, and turgidity of the neck, and small size of the trachea. Having performed the operation several times, under these circumstances, I can confirm the opinion of those Surgeons who regard it as only an unavoidable alternative between death and the possible preservation of life, and that the result is generally fatal, from the super-vention of bronchitis or pneumonia.

ASPHYXIA or APNŒA.—These terms are synonymous only by usage, as being understood to signify want of breath; their etymological meaning is widely different, the one signifying an absence of pulse (*à* not, *σφύζω*, I beat); the other, an absence of breath (*à* not, *πνέω*, I breathe). Apnœa should, therefore, correctly speaking, be the term selected to designate the various forms of suspended or impeded respiration; but the term Asphyxia has, by association, become so familiar that I here employ it as having that meaning.

*Symptoms*.—Dyspnœa or difficulty of breathing, as indicated by the

respiratory movements; which, at first short and rapid, soon become deep, forcible, and prolonged, with a gradually widening interval between them, until just before they entirely cease, when they again diminish in force and duration. The circulation of blood undergoes concurrent changes; the heart's action, at first accelerated, in a few seconds becomes slow, laboured, and feeble, till the pulse ceases to be perceptible at the wrist. The heart, however, still beats, audibly to the ear, and palpably to the hand, applied to the chest; this action gradually becomes less and less distinct, till it entirely stops at a period within ten minutes after the first interruption to the respiration. The period that elapses between the last respiratory effort and the cessation of the heart's action, varies from two to four minutes. Cerebral symptoms accompany the circulatory changes, and in somewhat the following order:—a sensation of fulness in the head and giddiness, singing in the ears, and flashes of light dancing before the eyes; then follow pleasing almost voluptuous dreams, which soon fade away into insensibility and unconsciousness, speedily succeeded by convulsions. The *appearances* of the person undergoing asphyxia are peculiar;—an extremely anxious expression of countenance, blueness of the lips, starting of the eyeballs, distension of the vessels of the face, head, and neck, frothy mucus, occasionally sanguineous, about the mouth, involuntary passage of the feces and urine, and sometimes an emission of semen with or without erection.

All the symptoms are modified and proceed more or less rapidly, according to the cause of asphyxia.

*Post-Mortem Appearances.*—The *external* appearances depend on the period after death,—in the course of twelve hours, any characteristic appearances will mostly have passed off; and they are modified by the cause of fatal asphyxia. At an *early* period,—within three or four hours after death, lividity of the lips, with oozing froth, and perhaps slightly sanguineous mucus are conspicuous; lividity and swelling of the tongue, which presents impressions of the teeth upon its margin, may also be observable; the eyelids are half open, and the pupils dilated; but the countenance is generally placid and pallid, or faintly livid. These appearances, however, resemble the facial aspect of death from epilepsy; or they may, in part, proceed from heart-disease, concussion of the brain, and perhaps other causes of death. Rigor mortis sets in early, and particularly after *drowning* in ice-cold water. The hands are clenched, sometimes so firmly in the drowned, as to be opened only by great force, even to cause fracture of the finger bones. Death resulting from asphyxia mechanically induced, usually leaves some marks of violence, such as ecchymosis or laceration at the seat of injury. There may be the mark of a cord upon the neck after *hanging*, or of fingers on the neck after throttling; the hyoid bone also is sometimes fractured, or the cartilages of the larynx are dislocated. The *internal* appearances consist chiefly of venous congestion of certain organs, with a proportionally anæmic condition of other organs. The heart and great vessels present great engorgement with black blood, on the right side, in both the auricle and ventricle and extending to the large vessels connected therewith; the left side of the organ generally being empty, or containing venous blood as on the right side. The blood throughout the body has a venous tint, and is sometimes found in a fluid state. The portal system is greatly engorged, and thence the liver and spleen more especially. The kidneys partake of the general venous congestion. The lungs are not so entirely nor in-

variably congested as has been asserted in most works; and the brain,—according to the results of experiments on animals, by Ackermann,—is always in an anæmic condition; the cerebral vessels becoming congested merely as the mechanical result of the post-mortem distribution of the blood, in consequence of a dependent position of the head. Extravasations of blood within the cranium, occasionally result from injury to the head in the mode of death.

Death by *drowning* presents one peculiarity in the state of the air-passages and lungs; these organs contain water, or other foreign matter, as mud, duckweed, &c.; there being no exclusion of foreign matter by spasm of the glottis, as was formerly supposed. This admission of foreign matter is established by the observations of the Committee of Inquiry appointed by the Royal Medico-Chirurgical Society, and whose Report appeared in the Transactions, 1862.

The *causes* of asphyxia may be arranged under four general heads; (1) A mechanical impediment to the entrance of air into the lungs; (2) drowning; (3) the absence of oxygen in the respired gas; (4) inhalation of a toxic vapour, associated with an absence of oxygen. The following tabulated view—constructed by Dr. George Harley—presents, at a glance, a very useful enumeration of the particular causes of asphyxia, comprised under each of these general modes of causation.

*Asphyxia may arise from—*

1st. Mechanical Impediment to the Entrance of Air into the Lungs.	Accident.	External.	{ Pressure on the trunk preventing the expansion of the chest; throttling; garotting; strangulation by a cord; hanging; smothering, by covering the mouth and nostrils, imbedding the face in earth, feathers, wool, &c.; paralysis of the respiratory muscles from injury to the spinal cord, or to the base of the brain; double penetrating wound of the chest, admitting air.
		Internal.	{ Choking from a morsel of food or other substance blocking-up the fauces; plugging of the trachea by a cherry-stone or other substance; constriction of the fauces and injury to the glottis from application of corrosive and irritating fluids.
	Disease.	External.	{ Pressure on the trachea from an aneurism or other tumour.
		Internal.	{ Edema of the glottis; tumour on or about the vocal cords; false membrane blocking-up the air-passages, as in diphtheria or croup; bursting of an abscess or aneurism into the trachea; double pneumonia or pleurisy; accumulation of mucus in the bronchial tubes; apoplexy at the base of the brain or in the medulla oblongata, causing paralysis of the pneumo-gastric, and of the respiratory muscles.
	2nd. Drowning . . . . . { In any liquid of whatever nature—water, wine, beer, or brine.		
	3rd. Absence of Oxygen in the respired gases. { Inhalation of pure nitrogen, hydrogen, or any other innocuous gas.		

4th. Inhalation of a toxic gas or vapour.	{	In which death is erroneously attributed to Asphyxia.	{	Carbonic acid, carbonic oxide, coal-gas, choke-damp, ammonia, chlorine, sulphuretted hydrogen, arseniuretted hydrogen, antimonuretted hydrogen, sulphurous acid, nitrous acid, hydrocyanic acid, vapour of chloroform, ether, amylene, or any other volatile product.
---	---	---	---	---

*Treatment.*—The primary indication is to arterialize or oxygenate the blood as soon as possible; this implying the restoration of respiration, and circulation—by certain resources, any adverse condition having been previously removed.

*Artificial Respiration.*—This may be effected by various apparatusless means, and which, therefore, are always applicable.

(1) By simultaneous pressure on the abdomen and thorax, alternated with relaxation, twenty or thirty times *per* minute. The compression should be made over the lower part of the sternum and upper and middle part of the abdomen, so as to partially expel the air from the thorax, without allowing any counteractive effect by descent of the diaphragm; the resilience of the thoracic walls enables the air to rush into the lungs, and then compression is repeated. If food be forced up from the stomach, the patient should be placed on his face for a few seconds, while any such matter is expelled, lest it pass into the wind-pipe.

(2) *Marshall Hall's method* — or the “ready method” — consists essentially in turning the body gently on the side and half prone, and then briskly on the face, alternately; and in making pressure along the back of the chest each time the body is brought into the prone position. This method has been largely practised and has proved very successful in restoring respiration. Yet its efficacy was not so favourably reported by the Committee of the Royal Medico-Chirurgical Society, the whole amount of exchange of air sometimes not exceeding a few cubic inches, and never exceeding 15 cubic inches.

(3) *Silvester's method*—or the “physiological method”—consists in the imitation of the natural action, as during deep inspiration, of the pectoral and other muscles passing from the shoulders to the walls of the chest. Inspiration is imitated by slowly extending the arms upwards by the sides of the head until the elbows nearly touch each other; expiration is then performed by simply restoring the arms to the sides of the chest, and pressing them against it, or pressure on the lower part of the sternum will have the same effect and more readily than lateral pressure with the arms. This method seems superior to Marshall Hall's in two important elements; the *first* step in the restoration of breathing is a movement of expansion to a chest already in a state of expiration; and *both* sides of the chest, are left uncompressed and free to expand. The quantity of air thus exchanged often exceeds 30 cubic inches, and in one instance amounted to 50 cubic inches.

*The circulation.*—Restoration of this function is partly effected by that of respiration—by arterialization of the blood and the respiratory movements. But certain special means of stimulation should also be resorted to; such are warm frictions all over the body and more especially on the limbs; warm coffee or tea, and brandy, when the patient can swallow, should be administered, or previously by the stomach-pump, and stimulant enemata also prove serviceable; also a warm-bath, not above 106° Fahr., when the temperature of the body is much reduced, as by

drowning in the winter season. Artificial respiration by pressure can be readily applied while the body is in the bath.

As soon as the natural respiratory movements recommence, artificial respiration may be discontinued, or renewed only to aid the efforts when feeble and imperfect.

*Treatment after natural Respiration.*—The following directions are appended by Dr. Harley.—(1) Give the patient some warm nutriment, to which a small quantity of stimulant is added; beef-tea, chicken-soup, coffee, or tea with one or two tablespoonfuls of brandy. (2) Put him into a well-aired bed with hot bottles to his feet, and encourage sleep. (3) Let him be carefully watched during sleep in case of secondary apnœa; at the slightest symptom of which let gentle frictions, and, if necessary, artificial respiration be again had recourse to. Give volatile stimulants, such as the spiritus ammoniæ aromaticus, or sp. atheris nitrici.

In the case of the *drowned*, the following might be said to be the four golden rules of treatment:—(1) Empty the air-passages of all the water and frothy mucus they may chance to contain, by holding the legs and trunk higher than the head. (2) Wipe the mouth and nostrils dry. (3) Draw forward the tongue. (4) Use artificial respiration.

**PHARYNX and ŒSOPHAGUS.**—*Wounds* of the gullet occur, most frequently, in connexion with cut-throat, as a complication of this form of injury.

*Foreign Bodies.*—Various substances are liable to become impacted in the pharynx or œsophagus; some of which obstruct the passage by their size, as a lump of meat; others impinging, by their pointed shape, as a fish-bone. The former substances stick, either in the pharynx, about opposite the larynx, where the tube is narrowed at the commencement of the œsophagus; or, low down towards the cardiac orifice of the stomach.

The *symptoms* are those of choking and suffocative cough, with turgidity and blueness of the face; and the foreign body can probably be felt on introducing the finger into the pharynx. If unremoved, asphyxia may soon prove fatal. Low down in the œsophagus a similar obstruction produces equal difficulty in the passage of anything swallowed, though not any difficulty in the act of deglutition itself; and a sense of oppression with pain about the top of the sternum, but the degree of actual suffocation will depend on the pressure of the impacted body on the trachea. The substance can be detected by the introduction of an oiled-probang, carefully passed down to the seat of obstruction.

Small pointed bodies commonly lodge in some fold of mucous membrane, behind the root of the tongue, between it and the epiglottis, or in the sides of the pharynx. Any substance so placed is felt by the individual, more particularly in the act of swallowing; and it may perhaps be seen, or felt with the finger.

*Complications, and Consequences.*—Rupture of the gullet has occurred, owing to the violence of impaction, or in consequence of ulceration with the formation of abscess in the cellular texture around the tube. Fatal hæmorrhage also has ensued. In a remarkable case, at the University College Hospital, many years since, a street-juggler passed, as usual, a long, round-ended sword down his throat; when he suddenly sprang into the air and fell in a state of collapse. In this state I saw him, on being brought to the Hospital; a loose emphysematous crackling could be dis-

tinctly heard, and even felt, under the sternum in the anterior mediastinum, during each hurried respiration. The poor fellow soon died, then it was found that the sword had obliquely perforated the œsophagus and pericardium at the base of the heart. As assistant-curator of the Museum at that time, it became my duty to make a preparation of this interesting specimen, which with the sword placed by its side in a long glass jar, is preserved in the Museum.

*Treatment.*—The foreign body impacted, must either be extracted or pushed down into the stomach; but which of these two proceedings may be proper will depend on the situation and nature of the substance.

In the *pharynx*, any kind of foreign body should be extracted, if possible. The patient being seated, with his head thrown back and mouth wide open; the Surgeon introduces his forefinger straight into the pharynx and searching for the substance, hooks it up with his finger, or by a hook-probang, (Fig. 367), or removes it with curved forceps guided by the finger. A pointed foreign body, as a fish-bone or a pin, must be withdrawn very carefully, lest it lacerate the pharynx. When any such body has been removed, a pricking sensation will still be experienced by the patient for a while. Low down in the *œsophagus*, an impacted foreign body may commonly be pushed into the stomach by means of a probang, (Figs. 368, 369), used gently; or perchance, by directing the patient to swallow a large mouthful of bread. But a rough substance which would

FIG 367.

FIG. 368.

FIG. 369.

thus rupture the œsophagus, or one of a metallic or other kind unsuited to the stomach, had better be drawn up gradually by the probang or forceps. Sometimes, an emetic will succeed in dislodging and ejecting the substance; or it has been dissolved, as in the case of a chicken bone, by swallowing large quantities of dilute acid. This, however, is obviously an objectionable proceeding.

All other means having failed, *pharyngotomy* or *œsophagotomy* must be resorted to for the extraction of the impacted substance.

Asphyxia may be so urgent that it will be absolutely necessary to perform *tracheotomy*, before attempting to remove the foreign body from the œsophagus. Generally, however, the attempt may be made at once; and thus I succeeded instantly in pushing a lump of gristly steak into the stomach of an elderly lady, who lay back on a sofa gasping for breath and was already black in the face.

**PHARYNGOTOMY and ŒSOPHAGOTOMY.**—These operations consist in opening the gullet at one or other part; either for the removal of an impacted foreign body, or occasionally in stricture, for the purpose of conveying food into the stomach.

The left side of the neck is usually selected, the œsophagus inclining rather to this side is there more accessible. An incision is made of sufficient length along the anterior border of the sterno-mastoid muscle, betwixt it and the trachea. The skin, platysma and cervical fascia having been divided, the dissection is carried directly backwards, avoiding the carotid sheath and larynx or trachea. The omo-hyoid muscle may be divided, but the thyroid arteries should, if possible, be avoided in this deep dissection. Having reached the pharynx or œsophagus, a bougie, sound or catheter, had better be passed through the mouth into the cavity, and made to project as a guide on which to cut the opening into the gullet. The aperture may then be enlarged, either by dilatation with forceps, or by further incision with a blunt-pointed bistoury, to an extent sufficient for the extraction of the foreign substance, or for the introduction of a feeding-tube.

## CHAPTER XLVI.

### DISEASES OF PHARYNX AND ŒSOPHAGUS; LARYNX AND TRACHEA.

**FAUCES.—TONSILS and UVULA.—TONSILLITIS.**—Acute inflammation of the tonsil, or ordinary “sore-throat” is denoted by diffused redness and rapid swelling of the tonsils, which may almost meet, leaving only a chink between them. Commonly only one tonsil is affected. Pain, at first not acute, but rather as if the part had been bruised, is diffused over the back of the mouth and much increased by any attempt at swallowing; tenderness also is felt in the side of the neck and under the angle of the jaw. The saliva accumulates in the mouth and dribbles away, the patient holding his mouth slightly open as if to relieve the sense of strangulation, and he speaks with a thick, nasal voice. The tongue is loaded with a creamy fur, and the breath fœtid; there is considerable throbbing head-

ache, and rather sharp fever. The state of the tonsils is readily seen on opening the mouth, by simply laying a spatula or the handle of a spoon on the tongue, which gradually contracts backwards, thus fully exposing the fauces. This practical hint for examining the throat is due to Mr. Pollock; depression of the tongue provokes a steady and firm effort of resistance, and thereby increasing the natural tendency of the organ to arch up when the mouth is opened, the tonsils can scarcely be seen.

The *causes* of acute tonsillitis seem to be exposure to cold in conjunction with some constitutionally disordered state of health, as a gouty habit, or disorder of the digestive organs. Frequently one tonsil being inflamed, the other becomes affected, and the individual is subject to recurring tonsillitis, usually on the same side.

The inflammation *terminates* in resolution, or not unfrequently in abscess, but rarely in childhood, apart from scarlet fever, and seldom in old age. Suppurating tonsillitis is more incident to youth and middle life.

*Treatment.*—Local measures consist in hot fomentations or a mustard poultice from ear to ear, and the inhalation of the steam of hot water; scarification of the tonsils may also be resorted to for the relief of congestion. But any constitutional state of the general health must be rectified, and without much lowering treatment. Abscess should be opened early,—as soon as a white speck in the tonsil becomes visible; and carefully, by a knife of limited or protected cutting edge,—not to wound the lips or tongue, and in puncturing the abscess, the edge should be turned towards the middle line, never outwards,—thus to avoid the risk of wounding the internal carotid artery outside the tonsil. The relief obtained is very great, and the inflammation soon subsides; leaving, however, the patient much pulled down, considering the shortness of the attack.

**CHRONIC ENLARGEMENT OF THE TONSIL.**—Resulting from repeated inflammation, this hypertrophied condition of the tonsil occurs mostly in children of a scrofulous constitution, and more commonly in females. Insidious and painless, the enlargement produces no symptoms otherwise than those arising from the mechanical occlusion of the tonsils. Hence, some difficulty of swallowing and breathing, the child snoring at night, and awaking in alarm; the voice is muffled and there is more or less “throat-deafness”; the intensity of these symptoms depending on the size to which the tonsils attain.

Ulceration frequently supervenes from time to time, and occasionally acute inflammation. The breath is often offensive, owing to decomposition of the sebaceous secretion accumulated in the crypts of the gland, or of the thick semipurulent mucus clinging to the fauces.

*Treatment.*—Constitutional measures are far more effectual than any topical applications. A general tonic plan of treatment, in the form of steel wine or the other preparations of iron, bark, cod-liver oil, and a nutritious, well-regulated diet. Sea-bathing is often most advantageous. Stimulating applications, as by nitrate of silver or gargles, can scarcely affect the condensed areolar or fibrous tissue of which the enlarged mass consists.

*Superficial Excision* of the tonsil is the only efficient local remedy; but it had better be reserved for an extreme state of chronic enlargement, when any of the already mentioned symptoms have become most inconvenient or detrimental to the general health. The mouth being held wide

open and the tongue gently depressed, the tonsil may be seized with a vulsellum, but not drawn out of its bed, and a thin slice removed with a protected blunt-pointed bistoury (Fig. 370); or the same partial excision

FIG. 370.

FIG. 371.

can be performed by means of a guillotine (Fig. 371). I prefer the latter, especially in children, in whom, although the mouth is comparatively small for the introduction of the instrument, yet it is a steadier mode of excision. Both tonsils may be operated on at the same sitting. Iced water will arrest the hæmorrhage; pressure and styptics of perchloride of iron or of turpentine may be necessary to stop any unusual or persistent bleeding.

The gland remaining after operation, shrinks eventually into its bed; the cut surface contracting by cicatrization.

**ELONGATION OR RELAXATION OF THE UVULA.**—Thickening, without elongation, of the uvula sometimes occurs; but an elongation or relaxation without thickening is the more common state. It appears to consist of an excess of mucous membrane, the azygos muscle not participating in the hypertrophy; and the membrane may extend an inch beyond the extremity of the muscle, hanging down as a thin narrow slip of this tissue, with a pointed extremity. When of this length, it dips into the pharynx and touches the aperture of the larynx. Constant irritation occasions a spasmodic cough, while tickling of the fauces excites nausea or even vomiting. The patient's life is sometimes thus rendered quite miserable. An elderly gentleman, otherwise remarkably hale and hearty, spoke to me of his depression as being intolerable.

The cause of this hypertrophy generally seems to be an habitual over-exertion of the voice, which probably throws in action the uvula. Hence its elongation is not uncommon among clergymen and barristers; not a few of whom, whether eminent preachers or advocates, are subject to this complaint. It arises also mostly in those of a gouty diathesis.

*Treatment.*—Stimulants and astringents topically applied have some beneficial influence. Nitrate of silver freely applied once or twice; or cayenne pepper, or alum, occasionally, blown through a quill on to the uvula, may prove useful. Tonic treatment of the general health is an important adjunct. The apparent causes adverted to must, of course, be removed when circumstances permit. Relaxation still continuing in spite of any such remedial measures; a portion of the pendent uvula must be cut off. This may easily be done by seizing the extremity with polypus-forceps, and snipping off with blunt-pointed scissors, so much as to leave the stump of the natural length of the uvula. A combination of forceps and scissors—an instrument of American invention—has been used for this purpose; thus holding and cutting the uvula simultaneously. This method is the same in principle as the removal of a nasal polypus with my “scissor-forceps.”

**TUMOURS OF THE VELUM PALATI.**—(1) *Fibro-cellular* tumour is usually attached to the free border or upper surface of the soft palate; having a pendulous, painless character, and being of slow growth, it may be discovered only when mechanically inconvenient by dropping down below and behind the root of the tongue.

This tumour can be removed with forceps and scissors; care being observed to snip it off at the pedicle, or as near as can be reached.

(2) *Cysts*, mucous or sebaceous, are sometimes met with in the soft palate; containing respectively, a thin glairy fluid, or yellowish-white fatty matter.

They must be laid open by a free incision, and their interior touched with a stick of nitrate of silver twirled round within the cyst, or with a probe dipped in nitric acid.

*Abscess* of the velum presents a globular swelling of the whole palate, accompanied by the red blush, and pain of inflammation. It must be opened early and freely with a sharp-pointed, protected bistoury.

**PHARYNX and ŒSOPHAGUS.**—**PHARYNGITIS.**—Inflammation of the pharynx, occurring generally as a continuation of a similar condition of the fauces and soft palate, but rarely as an independent affection, has an erysipelatous and diffuse character. It often terminates in purulent infiltration of the sub-cellular tissue, and even sloughing of the mucous membrane.

The *treatment* is similar to that of phlegmonous erysipelas; swabbing the pharynx with nitrate of silver and the employment of chlorinated gargles, must be reinforced by the administration of quinine with mineral acids, and as much nourishment and internal stimulants as can be got into the system. Laryngotomy may have to be performed, owing to œdema or spasm of the glottis rapidly supervening and impending suffocation. But, when purulent infiltration has taken place with considerable swelling, extending perhaps down the œsophagus to its cardiac end; swallowing becomes impossible, and recovery is almost hopeless.

*Abscess* occasionally forms in the cellular texture behind the pharynx, as a result or cause of some disease of the cervical vertebræ, or from ulceration of the pharyngeal mucous membrane by the impaction of a foreign body, as shown by a specimen in the Museum of St. George's Hospital.

The *symptoms* are difficulty of deglutition, and perhaps dyspnœa owing to pressure on the larynx; or nasal intonation, if the posterior nares be occluded. On examining the interior of the pharynx, a tense fluctuating

swelling may be seen and felt. This must not be mistaken for a polypoid or other solid growth of the walls or cavity of the pharynx. Pharyngeal abscess may burst into the mouth, or extend downwards under the sternomastoid muscles and present in front of the neck.

The *treatment* is simply evacuation of the matter by a well-timed and well-placed puncture with a sharp-pointed protected bistoury. The pus discharged has an offensive smell, not unlike that of a rectal abscess.

*Ulceration* of the pharynx is usually a manifestation of Syphilis or Scrofula, and as such, it forms part of the general pathology of these diseases, with the treatment accordingly.

**TUMOURS.**—*Fibro-cellular, fibrous, and fatty* tumours of the pharynx, are occasionally observed; giving rise to the symptoms of abscess—difficult deglutition, and perchance impeded respiration, with a swelling presenting in the pharynx, and perhaps in the neck. The characters of this swelling and its antecedent history will be the grounds of diagnosis. Practically, the particular kind of growth is less important than the size, shape, position, and attachment of the tumour. The pedunculated character generally prevails in pharyngeal tumours. *Epithelial* cancer is sometimes met with, in the usual flattened patches of this form of malignant growth.

The *treatment* of any pharyngeal tumour must be early removal by operation—a proceeding of much hazard, and necessarily restricted to the pendulous form of growth. Laryngotomy may have to be performed, prior to drawing the tumour forwards over the larynx and excising it through the mouth. Pharyngotomy might be preferable to this double operation, if the tumour be thus more accessible.

**STRICTURE OF THE ŒSOPHAGUS.**—This condition may be the result of certain distinct diseases of the œsophagus, producing a contracted state of this tube; which is commonly designated *organic* or permanent stricture to distinguish it from *spasmodic* stricture of the œsophagus.

(1) *Organic* stricture may be of *traumatic* origin—a *cicatrix* resulting from ulceration produced by the impaction of a foreign body, or occasioned by swallowing some acrid poison, as sulphuric acid; the latter mode of origin giving rise to a valvular *fold* of the mucous membrane, as in intestinal stricture consequent on dysentery. *Diseased* conditions comprise *fibrous* thickening, and *cancerous* thickening of the œsophagus. The cancer may be epithelial, medullary, villous, or colloid, and somewhat in this order of frequency.

*Symptoms.*—At first, a slight dysphagia or difficulty is experienced in the passage of solid food to the stomach. This increasing, the patient restricts himself to fluid food. At length, fluids are sipped only a few drops at a time, and perhaps partially rejected. Constant hunger, tortures the patient by day and night, yielding, however, at last to loss of desire for food; rapid emaciation and declining strength ensue. If ulceration takes place, expectoration of a semi-purulent and offensive secretion denotes this change, the breath also becoming perceptibly fœtid.

The cautious introduction of an œsophageal bougie will declare the existence of a stricture; the bougie comes to an obstruction or passes with difficulty. The *kind* of stricture must then be determined. Fibrous stricture presents a limited and smooth extent of contraction; no pus or blood follows the withdrawal of the instrument, but simply mucous discharge; there is no tumour in the neck, no cancerous enlargement of the cervical glands, nor cachexia. Carcinomatous stricture differs or contrasts

in all these particulars; a larger and irregular surface of contraction, through which the bougie passes roughly; pus and blood or the latter more especially, with shreds of tissue, follow the withdrawal of the instrument; while an elongated tumour is generally found at the root of the neck, with cancerous enlargement of the cervical glands, cancer also in some other part or organ, and cancerous cachexia.

(2) *Spasmodic* stricture is distinguished by the intermittent character of the contraction; it being sometimes present, sometimes absent, and situated rather in the pharynx than the œsophagus. The dysphagia intermits, and seems to be influenced mainly by the patient's attention being directed to or diverted from the complaint; the other symptoms—hunger, emaciation and loss of strength are far less pronounced. It occurs mostly in hysterical females. The introduction of a bougie is at first resisted, but the stricture soon yields under gentle pressure; and there are none of the additional and distinctive symptoms of fibrous or cancerous strictures.

*Dysphagia* may be *unconnected* with stricture, but dependent on some extrinsic cause or causes which diminish the calibre of the gullet by compression or obstruction. Such are; tumours connected with the pharynx; morbid conditions of the larynx—*e.g.* œdema; tumours in the neck; aneurism of the aorta or of the innominate artery; intra-thoracic tumours; dislocation of the sternal end of the clavicle backwards; impaction of a foreign body in the gullet. The diagnostic differences of these various causative conditions may be gathered from other sections of this work, pertaining thereto.

*Treatment.*—*Organic* stricture, of whatever kind, is incurable. *Dilatation*, by means of bougies, increasing in size, may afford partial and temporary relief. But the risk of perforating the œsophagus should be remembered, a risk proportionate to the structural disorganization and contraction of the passage; and this fatal misadventure has happened in the hands of the most skilful Surgeons. The instrument has been known to find its way into the mediastinum, into the cavity of the pleura, or into that of the pericardium. The principal use of a bougie is to determine the existence of a stricture, its situation and nature, and thus to complete the diagnosis of this affection; due caution being observed in passing the instrument.

When the result of cicatrix, or supposed folds of mucous membrane, caustic has been applied.

Nutritive enemata will tend to support the strength and prolong life; while washing out the mouth with whatever fluid is most relished, and swallowing perhaps a little of it from time to time, proves an agreeable occupation to the patient. In cancerous stricture, laudanum, or other anodynes administered in the enemata, will assuage the additional sufferings of this condition.

*Spasmodic* stricture is amenable to the general constitutional treatment of Hysteria. Large doses of assafoetida have been very advantageously employed by Dr. Garrod.

*Gastrotomy* or the operation of opening the stomach by an incision through the abdominal walls, has been performed, for the purpose of directly introducing food into the organ, when the œsophagus is impassable. Practised principally by Sédillot, Fenger of Copenhagen, Cooper, and Forster; the first-named authority thus performs this operation:—The patient lying on his back, the Surgeon standing on the right side,

makes a crucial incision, each line of which is about one inch and a half in length, on the left side of the mesial line of the abdomen; two fingers' breadth to the inner side of the costal cartilages, and about one-third nearer to the ensiform cartilage than to the umbilicus—having previously satisfied himself by percussion and palpation that the liver is not in his way. The dissection is carried through the abdominal wall, and the peritoneum opened. Then feeling with his left index finger for the left border of the liver, by following this upwards, the stomach is reached. The organ is seized with forceps, drawn forwards, and its structure recognised. The anterior wall of the organ is then fixed to the edges of the integumental aperture, by three or four points of suture, and an opening made into it about midway between its two extremities and a little above the lower margin. When, in the course of a few days, union of the wall of the stomach to the parietal peritoneum has become securely established, nutritive injections are administered through a silver tube passed into the artificial aperture, and which is thus kept patent. The value of this operation has yet to be decided by the results of further experience.

**PARALYSIS OF THE ŒSOPHAGUS.**—This affection occasions inability of swallowing; but it is unattended with spasm or pain, and the introduction of a bougie meets with no obstruction. It generally depends on centric disease, either of the brain or spinal cord. Cure will, therefore, probably be impossible.

*Treatment* consists in the administration of nourishment by the stomach-pump, or enemata. Electricity has sometimes proved temporarily beneficial. Strychnia and other nervine tonics might perhaps be tried with advantage.

**DILATATION AND SACCULATION.**—These conditions of the œsophagus are of rare occurrence. Instances of the former have been recorded by Rokitsky in his *Pathological Anatomy*, and by Dr. Barker in the *Pathological Society's Transactions*—tenth volume. A remarkable specimen of sacculation is preserved in the Museum of University College; it was the first preparation I put up on becoming Assistant-Curator. The mucous membrane protrudes through the fasciculi of the muscular coat in the form of very distinct pouches.

The *symptoms* of either structural condition are marked dysphagia, of a mechanical kind, the food lodging more especially in the pouches of a sacculated œsophagus. The ingesta seem to stuff in the chest, without reaching the stomach, and a portion is soon vomited, or rather ejected from the œsophagus.

*Treatment* cannot be curative. Feeding by the tube of the stomach-pump, or per rectum, is the only resource.

**USE OF THE STOMACH-PUMP.**—The flexible tube of this apparatus is to be introduced cautiously down the back of the pharynx and œsophagus; a gag, with a hole in it, having been placed in the patient's mouth, for the easy passage of the tube without any compression by the teeth. The stomach is then injected moderately full with water by working the pump, a pint or two being thus thrown in, and then pumped up again by reversing the action of the instrument. Care must be observed not to withdraw the whole quantity injected, lest the mucous membrane of the stomach be sucked up into the apertures of the tube, as would happen if the stomach were empty. Water should be thrown in and withdrawn, until it returns colourless and the stomach is completely washed out. Emetics are generally preferable to this artificially mechanical mode of

evacuating the stomach, whenever vomiting can be *excited*, assisted by freely swallowing diluents.

Such is the application of the stomach-pump in cases of *poisoning*. Its application for the administration of liquid *food* is similar, only that the liquid is simply injected and not withdrawn.

**LARYNX and TRACHEA.—LARYNGITIS.**—Inflammation of the larynx is attended with more or less urgent dyspnœa and aphonia or loss of voice, with difficult deglutition; which are proportionate to the effusion and swelling.

*Acute* laryngitis affects principally the mucous membrane of the larynx; the variety *Œdematous* laryngitis affecting chiefly the sub-mucous cellular tissue, especially of the glottis.

*Chronic* laryngitis, resulting in thickening of the mucous membrane of the glottis and over the back of the thyroid cartilage, is attended, more particularly, with aphonia or various modifications of the voice, as hoarseness, squeaking or broken voice, and with tickling, spasmodic cough. This form of the disease is common among clergymen, barristers, and public singers; and it goes by the name of "Clergyman's sore-throat."

*Consequences.*—The usual consequences of inflammation may follow laryngitis; abscess, sloughing and ulceration of the mucous membrane, possibly caries and necrosis of the cartilages of the larynx.

*Diagnosis.*—Visual examination of the larynx can be made directly, by seating the patient opposite a good, clear, white light, depressing the root of the tongue with a spatula, and requesting the patient to draw a deep breath. The laryngoscope supplies the means of completely exploring the larynx. Its application will be explained in connexion with the Treatment of Laryngeal Affections.

**SPASMODIC AFFECTION** of the larynx is accompanied with dyspnœa and other symptoms of laryngitis, thus simulating this disease. But the symptoms are less urgent, and also intermittent. This affection occurs not unfrequently in children, as spasmodic croup; and in adults, especially young hysterical females. It may also be concomitant with Laryngitis, or a sympathetic affection resulting from irritation or pressure on the laryngeal nerves by aneurism or tumour.

**TUMOURS.**—Polypi, fibro-cellular, fibro-plastic, or epithelial, and attaining perhaps to the size of a hazel-nut, may be attached to the epiglottis or to the mucous membrane within the larynx or trachea.

The *symptoms* of any such polypoid growth are; hoarseness or other modification of the voice, tickling, spasmodic cough, and increasing dyspnœa. But the difficulty of breathing varies, in the same case, at different times; fits of suffocation coming on, whenever the tumour, if attached to the epiglottis, is drawn down by inspiration, or, if within the larynx, it is driven up between the rima glottidis by expiration. A valvular flapping sound, heard or felt, during respiration, is the most distinctive symptom. The tumour, or a portion of it, has occasionally been coughed up, thus determining the diagnosis. Laryngeal growths are more fully described in Sir Duncan Gibb's well-known special work on Diseases of the Throat, &c., and in the Jacksonian Prize Essay on the Pathology and Treatment of Diseases of the Larynx, by Dr. Morell Mackenzie.

**THE LARYNGOSCOPE.**—This is an instrument for obtaining a view of the interior of the larynx during life. The construction of the apparatus in its present form, as fitted for the art of laryngoscopy, is due to Professor Czermak of Pesth; but the history of the laryngoscope dates back indi-

rectly to M. Lerret, a distinguished French accoucheur, who in 1743, invented a laryngeal speculum or mirror. Subsequently, other names are more or less associated with this invention; Bozzini in 1804, and Senn in 1827; while Dr. Benjamin Guy Babington in 1829, brought out the first laryngoscope, or glottiscope as he named it; a laryngeal mirror combined with another mirror, held in the operator's hand, as the means of illumination. Bennati, in 1832, asserted his ability to see the vocal cords with an instrument devised by Selligue, a mechanic; whose contrivance was "a double-tubed speculum, of which one tube served to carry the light to the glottis, and the other to bring back to the eye the image of the glottis reflected in the mirror, placed at the guttural end of the instrument." Baumès in 1838, Liston in 1840, and Dr. Warden in 1844, were each successively associated with the art of laryngoscopy; and in 1844, the late Mr. Avery devised a laryngoscope whereby artificial light was made the source of illumination. In 1854, M. Maunul Garcia conceived the idea of employing mirrors for studying the interior of the larynx during singing, and by autoscopic examination. In 1857, Dr. Türk of Vienna, endeavoured to employ the laryngeal mirror, alone, in the wards of the General Hospital; and later in the same year, Czermak completed the construction of the laryngoscope, and brought it into use in practical medicine.

The foregoing historical sketch is gathered from Dr. Morell Mackenzie's excellent work on the subject; and the following descriptive account of the instrument and method of using it, is derived from the same source.

The laryngoscope consists of two parts: (1) a small mirror fixed to a long slender shank, which is introduced to the back of the throat; and (2), an apparatus for throwing a strong light, solar or artificial, on to the small mirror. For thus projecting the luminous rays, most laryngoscopists employ a second, larger mirror, which reflects the light from a lamp or the solar rays. When artificial light is employed, this illuminating mirror is slightly concave; when sunlight is used, its surface is plane.

The only principle concerned in the art of laryngoscopy is the optical law, that when rays of light fall on a plane surface, the angle of reflexion is equal to the angle of incidence.

*Laryngoscopy* is thus performed:—The patient should sit upright, facing the observer, with his head inclined very slightly backwards. The observer's eyes should be about one foot distant from the patient's mouth, and a lamp burning with a strong clear light is placed on a table at the side of the patient, the flame of the lamp being on a level with the patient's eyes. The observer puts on the spectacle-frame with the reflector attached, in front of his forehead, and directing the patient to open his mouth widely, endeavours to throw a disk of light on to the fauces, so that the centre of the disk shall correspond with the base of the uvula. This projection of a luminous disk on to the back of the throat requires some practice, and it may be facilitated by inclining the reflector at a suitable angle before putting on the spectacle-frame. The tongue of the patient should now be protruded, and held if necessary between the thumb and finger enveloped in the corner of a towel, to secure the hold; the observer then introduces the laryngeal mirror to the back of the throat, having previously warmed its reflecting surface slightly over the chimney of the lamp, in order to prevent condensation of the expired air. This introduction of the mirror, so as to avoid producing faucial irritation, is

a *manœuvre*—as the projection of a luminous disk on to the fauces might be called a *caput æneæ*—which requires some nicety of manipulation and practice. The handle of the mirror being held like a pen, it should be introduced quickly to the back of the throat, its face directed downwards, and away from the tongue; the posterior surface of the mirror should rest on the uvula, which is pushed upwards and backwards towards the posterior nares. The observer, raising his hand a little, and directing it outwards, towards the corner of the mouth, the inclination of the mirror is thus altered and its face brought more towards the perpendicular, while the hand is kept entirely out of the line of vision. But this rotatory movement should be effected slowly, so that it can be arrested directly the larynx comes into view. Ambidexterity is very desirable in introducing the laryngeal mirror, and absolutely essential in the application of remedies to the larynx. The patient should then be taught himself to hold out his tongue.

TREATMENT OF LARYNGEAL AFFECTIONS.—*Laryngitis* must be met by the ordinary treatment of Inflammation, promptly applied; blood-letting, by means of leeches to the larynx, being especially applicable in the *acute* form of the disease, and less freely in the *œdematous* variety; while in both, calomel should be administered speedily to affect the system, and thus arrest the inflammatory effusion which perils suffocation. Antimonial salines are useful antiphlogistic adjuncts. *Chronic* laryngitis is principally amenable to the topical application of a solution of nitrate of silver.

*Spasmodic* Affections of the larynx will mostly succumb to the treatment of Hysteria; but when such an affection is sympathetic of some remote source of irritation, it may be irremediable. In one instance, many years since, a young woman was gasping for breath, and seemed so nearly on the point of asphyxia, that I was induced to have immediate recourse to tracheotomy; but, having made the incision through the skin only, over the trachea, respiration suddenly became free and the purple flush of the face disappeared; I at once discontinued the operation. When the bowels had been thoroughly evacuated of scybalous matter, and this source of intestinal irritation removed, the dyspnœa never returned.

*Polypoid tumours* of the larynx, illuminated by the laryngoscope, have been removed by various operative procedures. Sir Duncan Gibb has succeeded in casting a loop of thin silver-wire around the base of such a growth, situated just within the true vocal cords, and then detaching it by tightening the wire-ends drawn through a canula. Previous administration of the bromide of ammonium, in full doses, seemed to have the power of lessening the sensibility of the pharyngeal mucous membrane, and thus facilitating this operation. Dr. Walker of Peterborough, and M. Moura-Bourovillov in Paris, have also removed these laryngeal growths.

*Application of a Laryngeal Probang*.—Chronic laryngeal affections, principally of an inflammatory character, are much relieved or cured by the topical application of a solution of nitrate of silver, varying in strength from two to four scruples, and usually the latter proportion, to the ounce of distilled water. This can be applied by means of a laryngeal probang, consisting of a thin whalebone rod curved towards one end, to which is firmly secured a small, round, compressed piece of sponge. The mouth of the patient being opened, and the root of the tongue depressed with a

curved spatula; the sponge end of the probang, dipped in the solution, is passed down to the larynx, and the diseased part swabbed as much as may be necessary.

Can an instrument enter the larynx? is a question which has elicited considerable investigation and provoked much discussion; occupying a large proportionate space in one or two Text-books of Surgery.

A special Commission of the New York Academy, appointed to investigate this question, arrived at the conclusion:—"That there is no reliable evidence that the sponge-probang has been ever passed through and beyond the vocal cords."

Other modes of applying nitrate of silver have been proposed and occasionally practised. Injection of a solution by a laryngeal syringe has the advantage of gaining access to the interior of the larynx, or it can be applied to the pharynx or thrown up behind the velum and into the posterior nares. Inhalation of nitrate of silver in powder can be effected by means of a glass tube bent at one end, into which a small quantity of the nitrate—one part to ten or twenty of sugar having been placed—the tube thus charged is introduced into the mouth and directed over the epiglottis, the orifice of the straight part of the tube being closed with the finger. On raising the finger, and the patient making a sudden inspiration, the powder is drawn out of the tube into the larynx.

**LARYNGOTOMY and TRACHEOTOMY.**—The windpipe may be opened by surgical operation; either to establish Artificial Respiration for a time, or occasionally, to remove a foreign body from this tube. According to the situation of making the artificial aperture, the operation is designated: Laryngotomy, when the crico-thyroid membrane is thus opened; Tracheotomy, when the trachea is the seat of operation.

The various conditions of injury or disease which cause a mechanical impediment to the respiration, and which may require either of these operations for relief, have been noticed in other parts of this work.

*Laryngotomy* is very readily performed. The head of the patient being thrown back, the depression between the thyroid and cricoid cartilages is easily touched with the point of the finger. A vertical incision is made in the middle line, about an inch long, with a narrow-bladed, pointed bistoury or scalpel; this incision passing between the sternothyroid muscles, a cross cut through the crico-thyroid membrane, at once enters the air-passage. The air rushing in and gushing out of the aperture, and the immediate freedom of the respiration, shows that the object of the operation is accomplished. A curved laryngotomy tube of suitable size should be introduced, and retained by tapes fastened around the neck. Very little hæmorrhage occurs, but a small branch from the superior thyroid artery, running across the membrane, may be divided and require torsion or ligature.

*Tracheotomy.*—This operation consists in cutting down upon the trachea, in some part of its extent, and then dividing two or three of its cartilaginous rings; a more difficult and perhaps dangerous proceeding than laryngotomy, particularly if the neck be short and fat, the veins turgid, and the trachea deep, small, and restless,—moving up and down with each effort of hurried and forcible respiration. All these adverse conditions attend the operation in children.

The head being thrown back, an incision is made exactly in the middle line of the trachea, about an inch and a half to two inches long, extending from the lower margin of the cricoid cartilage downwards nearly to

the top of the sternum (Fig. 372). The skin, superficial fascia and fat, are thus divided; the opposed margins of the sterno-hyoid and sterno-thyroid muscles are then separated with the scalpel, and the veins in front of the trachea drawn out of the way to either side; any unusual artery discovered by its pulsation under the finger is also avoided. The isthmus, or connecting central portion of the thyroid body, may have to be drawn upwards; if wounded the hæmorrhage thence arising might be very troublesome.

FIG. 372.

A tenaculum or sharp hook is dipped into the upper part of the trachea, which is thus drawn a little upwards and steadied on the stretch; then, taking advantage of a favourable moment of exposure, the Surgeon penetrates the knife, with a slight jerk, into the lowest exposed portion of the trachea, and carrying a small incision upwards divides two or three of the cartilaginous rings of this tube.

FIG. 373.

The air rushing in and out again, shows that the windpipe is opened; but special care should be taken to avert any oozing of blood, arterial or venous, into the trachea; and a curved tube of a conical shape, flattened laterally as recommended by Liston (Fig. 373), should be introduced into the tracheal aperture, of sufficient size to completely fill it, and allow of free respiration, without, as Trousseau remarks, any whistling noise.

FIG. 374.

The introduction of the tube is sometimes attended with difficulty, owing to the elasticity of the tracheal rings partially closing up the aperture in making the attempt. One side of the incision in the trachea may be held aside with a hook, while the tube is slipped in; or the aperture

may be made and expanded with M. Garin's trachea-forceps dilator (Fig. 374); or Dr. Fuller's bivalve tube (Fig. 375) can be readily introduced,

FIG. 375.

closed, and a canula passed through it. A *double* tube is always preferable to a single one, especially if there be much expectoration; the inner tube can be taken out and cleansed. The tube is retained by tapes round the neck. Whenever the patient wishes to cough or speak, he must be instructed to close its orifice with his finger.

The final removal of the tube is determined by two events; the establishment of natural laryngeal respiration, and the cessation of any oozing hæmorrhage which might trickle into the tracheal aperture. When the tube is withdrawn the wound heals more or less readily.

The removal of any *foreign body* from the larynx or trachea must of course be effected before passing in the tube, in either of these operations, if undertaken for this purpose. The exact situation of any such substance having been ascertained by passing a probe through the artificial opening in the windpipe, forceps of suitable size and shape are then cautiously inserted and the body extracted.

The various difficulties in connexion with tracheotomy have been sufficiently adverted to in the above description; but certain modifications of the operation may be noticed. They relate to the mode of *opening* the trachea by means of different instruments. Sir H. Thompson has devised a *tracheotome*: an instrument with two blades, joined by a hinge at one end, and at the other bent down at an angle and furnished with cutting edges, so nicely adapted together, that when compressed by a screw above, they form one edge. The point is introduced *transversely*, between the first and second rings of the trachea, the blades are separated by reversing the screw, making an opening sufficient for the passing in of the tube, and the tracheotome is withdrawn. A bent *tracheal trocar* and *canula* has been used; but this mode of proceeding is decidedly objectionable, by depressing the trachea without readily penetrating it and then entering with a plunge.

## CHAPTER XLVII.

### DISEASES OF THE THYROID GLAND. THE PAROTID GLAND. TUMOURS OF THE NECK.

**THYROID GLAND.**—(1) **BRONCHOCELE OR GOÎTRE.**—This condition is an enlargement of the thyroid body, existing in one of three forms:—as *hypertrophy* of the proper structure of the thyroid, or *simple* bronchocele (Fig. 376); cysts imbedded in the substance of the gland, containing a glairy or bloody fluid, and perhaps bearing indigenous growths on their interior, forming *cystic* bronchocele; or as an enlargement of the thyroid vessels in and around the gland, constituting a vascular swelling, or *pulsating* bronchocele, and as being associated with an unnatural prominence or protrusion of the eyeballs and anæmia, this form of the disease is sometimes known as *exophthalmic* bronchocele. The state of the eyeballs has been referred

to an enlargement of the eye itself, Dr. Stokes attributing the prominence to an increase of the vitreous and aqueous humours; but it is generally referred to some morbid condition of the structures in the orbit, behind the globe,—effusion of serum, increase of post-ocular fat and cellular tissue, congestion of the orbital veins, or other allied cause. Combinations of these three conditions of bronchocele not unfrequently occur; cysts may be associated with hypertrophy, or vascular enlargement with cysts.

FIG. 376.

*Symptoms, and Diagnosis.*—Certain appearances and phenomena are common to all three forms of the disease. A swelling, corresponding in situation and shape to the thyroid gland, is presented in front of the neck; and which has a soft elastic character. Usually, both lobes of the gland are affected, and the tumour is bilobular; rarely, however, equally so; the right lobe is commonly the larger; occasionally, the middle lobe or isthmus is principally affected. The tumour always follows the movements of the trachea to which it is attached, and of the œsophagus as connected therewith; the swelling therefore rises upwards towards the chin when the patient is directed to swallow, and then lowers again to its original position as the act of swallowing ceases. This rising and falling of a tumour in the neck during deglutition is diagnostic of bronchocele from any other tumour, not implicating the thyroid gland, or directly attached to the trachea. When bronchocele has attained to a large size, this phenomenon is less observable, and therefore less characteristic. The skin over the tumour is not discoloured, or in an otherwise unhealthy state.

The *mechanical* results of pressure on surrounding parts are proportionate to the size of the tumour. Difficulty of breathing, especially in a stooping posture, and of swallowing, or dyspnœa and dysphagia, with some congestion of the brain, arise from pressure on the trachea, œsophagus, and jugular veins; hacking cough also ensues from a diseased condition of the trachea itself.

*Cystic* bronchocele is distinguished from simple hypertrophy of the thyroid or ordinary bronchocele; by tension and fluctuation in the cystic portions of the enlarged gland, and by a somewhat specially lobulated character, where the cysts partially project. The most marked instance of this form of the disease I ever saw, was in the Norfolk and Norwich Hospital, when I happened to visit that institution in the autumn of 1868. The patient, a young woman, was the subject of an enormous cystic bronchocele, which occupied the whole front and depth of the neck; extending laterally upwards from near the angle of the jaw on either side, downwards towards the clavicle, and from almost the level of the chin to the sternum. The whole mass looked like a pillow in front of the neck, tucked up under the jaw. The cysts were large, plainly fluctuating, and prominent.

*Pulsating* bronchocele is thus distinguished from ordinary goitre:—The size of the tumour varies considerably with the general condition of the patient as to rest or excitement, and their effect on the heart's action; the tumour rarely becomes large enough to produce any great deformity; and the purring thrill and loud murmur in the tumour,

with jerking of the carotids, and the general symptoms,—palpitation of the heart and prominent eyeballs, will complete the diagnosis.

*Causes.*—Common bronchocele, hypertrophy of the thyroid gland, occurs mostly in women, and commences about the age of puberty, in this country. It is frequently associated with some derangement of the menstrual function, and with an anæmic state of the general health. Hence the females affected have a pallid, weak, miserable appearance. Pregnancy alone not unfrequently induces enlargement of the thyroid gland. Endemic influence is remarkable; the disease prevails in Derbyshire, Nottingham, and the chalky parts of England; in the valleys of the Alps, Apennines and Pyrenees. In Savoy, Switzerland, the Tyrol and Carinthia, there are villages in which all the inhabitants, without exception, have these swellings. The hygienic cause, generally assigned under these circumstances,—the use of melted snow or of water impregnated with calcareous or earthy particles, is not established with regard to the localities most productive of the disease. But it does arise in low, damp situations chiefly, and under hygienic circumstances favourable to anæmia and debility. The disease is often associated with cretinism and idiocy; seeming to have an hereditary character in imperfect physical and mental development.

Pulsating bronchocele is said to be independent of endemic influence. Injury to the neck has sometimes been noticed as an exciting cause of bronchocele, a twist or strain of the neck having, apparently, given rise to the disease.

*Terminations.*—Recent enlargement of the thyroid gland may disappear under treatment; but the disease is of very chronic character, and when it has continued for some years, it is mostly incurable. The pulsating form of bronchocele is apparently urgent, yet it very rarely proves fatal; unless accompanied with organic disease of the heart; dilatation and hypertrophy, particularly affecting the left side of the heart, and perhaps thickening of the auriculo-ventricular valves.

*Treatment.*—The *hygienic* conditions productive of the disease, must if possible, be changed; the patient being removed from a low damp situation to a more airy locality. *Medicinal* treatment should have reference principally to the constitutional condition—anæmia. Iron, particularly the sulphate, may be administered with marked benefit, and Dr. Murnay speaks highly of strychnia; but the curative efficacy of iodine was first shown by Dr. Coindell; and shortly afterwards Dr. Fyfe of Edinburgh discovered the presence of iodine in burnt sponge. Originally given as thus prepared, the iodide of potassium is now commonly prescribed. Topically also, iodine ointment or that of the iodide of lead, may be rubbed into the tumour with advantage; or the emplastrum ammoniaci cum hydrargyro can be applied. Generally, however, all local applications are comparatively useless. A seton has been employed successfully by Mr. Hey of New York.

*Ligature* of the thyroid arteries, as the nutrient vessels, has been had recourse to. The difficulty and danger of this operative proceeding, its very questionable results, and the probability of other arterial branches becoming enlarged; constitute serious objections thereto.

*Pulsating* bronchocele would be most appropriately treated by ligature. Injection of perchloride of iron has been serviceable, subject to the risk of considerable inflammation, suppuration, and pyæmia supervening.

*Cystic* bronchocele may be tapped here and there, and injected with

tincture of iodine, in order thus to induce inflammation and adhesive obliteration of the cysts.

Excision of the thyroid gland, should hardly be entertained; this operation is specially dangerous owing to almost uncontrollable hæmorrhage, and the disease does not affect the general health nor peril life. If resorted to, the operation must be performed by an incision in the middle line of the neck, so as to turn the tumour out of its bed, and ligature of the vessels as they are successively divided. Removal of any portion of the gland, as of the isthmus crossing the trachea, should be accomplished with similar precaution; and the remainder of the gland secured on either side by double ligature, previous to excision of the intervening portion.

(2) *Inflammation* of the thyroid is rare; it occurs spontaneously, perhaps, in scrofulous persons only.

(3) *Fibrous, cartilaginous, and osseous* formations, sometimes occur in this gland; *tubercle* is scarcely ever seen, and *cancer* in its medullary form is very exceptional. (Rokitansky).

(4) *Hernia Bronchialis* is occasionally produced by protrusion of the mucous membrane through the cartilages of the larynx or the rings of the trachea, as a result of violent exertions of the voice. Larrey met with it in French officers, and in the priests who, with their deep-toned voice, call the people to prayer from the minarets in Mohammedan countries—as I often heard them do at Scutari.

The tumour is soft and elastic, increased by any expiratory effort, and it often disappears on pressure. The support of a compress is the only curative treatment.

**PAROTID GLAND.—PAROTITIS OR MUMPS.**—An inflammatory swelling of the parotid gland, involving the sub-maxillary and sub-lingual glands; and usually affecting both sides of the neck. Some pain and stiffness accompany this glandular enlargement; but suppuration rarely supervenes, although the swelling may be very persistent. It migrates, occasionally—by metastasis, as it is said—to the testicle, or to the breast in the female. Commonly occurring in children, and sometimes in adults; the disease arises apparently from cold and damp, and has a slightly infectious character.

There is no danger in this affection, only considerable inconvenience.

The *Treatment* consists simply in the topical application of warm fomentation or poultice, and subsequently stimulating embrocations when the swelling has become quite indolent. Saline aperients and tonics form the constitutional treatment. The metastatic affections must be treated as similar inflammatory swellings of the parts attacked.

**TUMOURS.**—(1) *Glandular parotid tumour* is the most frequent tumour in connexion with the parotid gland. It is probably developed in one of the lymphatic glands lying over the parotid, or it may occasionally be developed in the fibrous envelope of the gland itself. It resembles the adenoid or glandular tumours connected with the mammary or prostatic glands, and is described by Bauchet as an hypertrophy of the parotid. It consists of fibrous tissue mixed with glandular elements, in which there are often portions of cartilage, and one or more cysts. A distinct capsule generally encloses and isolates the tumour.

This parotid tumour appears as a firm hard lump, situated generally below and behind the lobe of the ear, but sometimes in front of it. (Fig. 377.) Growing slowly, and displacing the parotid and the parts contained therein, the tumour becomes buried deeply behind the ramus of the jaw. Besides deformity thence arising, hearing and mastication are

interfered with; and perchance facial paralysis may occur on the affected side.

*Treatment.*—Removal of the tumour with a knife is the only cure, but the operation is both difficult and dangerous. A  $\perp$  incision will be most convenient; the vertical line passing down the posterior edge of the tumour,

FIG. 377.

where it is most safely approached. It has been known to recur a second and a third time, as in a case recorded by Langenbeck, at the end of a year, and again after five years the tumour was successfully extirpated.

(2) The parotid region is subject to other tumours, which however are not at all peculiar to this part of the body. Thus, we recognise—*fibro-cellular, fibrous, fatty, cystic, cartilaginous, and cancerous* tumours; as growths incident to the parotid region. (Fig. 378.)

The removal of any such tumour must be determined by its size and apparent connexions; a cancerous tumour being irremovable probably, owing to its infiltrating character.

*Excision of the parotid gland* is an operation scarcely to be entertained in a work on Surgery; the irregular connexions of the parotid, and the important structures passing through it—the external carotid artery and facial nerve, render the extirpation of this

FIG. 378.

gland a surgically-impracticable operation. Portions of the gland may be removed with an overlying tumour.

**TUMOURS OF THE NECK.**—(1) *Enlargement of the cervical glands*, in scrofulous persons, is a common surgical affection; presenting round, puffy or indurated, sub-maxillary lumps; indolent or suppurating. A chain of rather large, rounded tumours, along the anterior margin of the trapezius, on both sides of the neck, is said by Miller to be characteristic of syphilis; and these lumps, though indurated, never suppurate. They are sometimes the first symptom, and the last to go, of any constitutional symptoms. Glandular enlargements of stony hardness, and involving the whole lymphatic chain, may be conjoined with exophthalmic goitre, as a result of the anæmic condition. Such enlargement resembles scirrhus affection, but has a totally distinct origin.

(2) *Induration of the sterno-mastoid muscle*, is not uncommon in children. It may be distinguished from any enlargement of the cervical glands, which lie posterior to the muscle, by two circumstances; in the one case, the swelling is within the sterno-mastoid, and its mobility varies with the contracted and relaxed state of the muscle; in the other case, the swelling is behind the muscle and is unaffected by its action.

This muscular affection is very curable in childhood, by counter-irritant and tonic measures; while glandular enlargements are obstinate and may be quite incurable.

(3) *Enlarged Bursæ* are found in the anterior part of the neck, although rarely. These bursal tumours may be situated in front of the pomum Adami, or between the posterior surface of the hyoid bone and thyroid cartilage, or between the muscles of the tongue. The tumours rise and fall in the movements of deglutition, thus resembling cystic bronchocele; but their situation is partly distinctive, and puncture will determine the diagnosis, by the nature of the contained fluid.

*Treatment* consists in blisters, puncture and injection of iodine.

(4) *Cysts* singly, or aggregated and forming a multilobular tumour,—known as hydrocele of the neck,—may occur in either triangle of the neck, commonly the posterior triangle, or beneath the sterno-mastoid muscle. Such cyst or cysts may be situated superficially, usually more deeply; and sometimes become so numerous as to occupy the whole side of the neck. The contents of the cysts are various; serous, or sanguineous fluid of a brownish colour, or sebaceous matter. (Langenbeck.)

The characters of the tumour thus formed are always similar; a tense and elastic, round or somewhat lobulated swelling; varying in situation, prominence and size. Deglutition and respiration may be more or less impeded. The diagnosis from *abscess* will be determined by puncture.

FIG. 379.

*Treatment.*—Tapping and injection with iodine. Suppurative action by means of a seton may be equally curative, but it is more hazardous. Extirpation will scarcely ever be practicable, owing to the situation of these cysts.

(5) *Fatty* tumour (Liston) (Fig. 379), *fibrous* tumour, *cartilaginous* tumour (Spence), and *cancerous* tumours, are occasionally met with in the neck; *epithelial* cancer, rarely.

The removal of these growths must be guided by general principles, having regard to the situation and connexions of the growth.

## CHAPTER XLVIII.

### INJURIES AND DISEASES OF THE SPINE.

THE Anatomical construction, and the Physiological or functional uses of the several parts, of the Spine or Vertebral column, should be remembered, in relation to its Injuries and Diseases.

*Anatomically*, the Spine—so named from the series of spinous processes presented posteriorly—consists of three elementary portions; the columnar portion, the canal, and the processes, articulatory, and those for the attachment of muscles.

The *functions* or *uses* of the Spine are threefold, and correspond to its anatomical elements. It is, a *column* or pillar for sustaining the weight of the head and trunk, at the same time being a girder to support the ribs, and connect the bones of the extremities; an *elastic-jointed* mechanism for flexible motion; and an *osseous canal* for containing and protecting the delicate, and vitally important structure of the spinal cord. But the integrity of the cord is also secured by three other special provisions. Firstly, by its central position in the vertebral column, the cord occupies neutral ground in relation to the forces which might cause sprain or fracture; in compression of the column forwards, and laceration of the posterior segment, the cord remains centrally, in a neutral state. Secondly, the elastic and graduated flexibility of the column, prevents the effects of shock, and abrupt motion, being communicated to the cord. Thirdly, its loose suspension in the canal, and enclosure in a layer of sub-arachnoid fluid, which acts as a water-cushion, will further resist concussion.

The flexibility of the vertebral column varies in different regions, the cervical, dorsal, and lumbar; being least in the dorsal region, where compared with the length of this portion of the spine, there is a smaller proportion of inter-vertebral substance than in the cervical and lumbar portions of the column. To compensate for these various degrees of flexibility, certain curves are introduced near the respective junctions, to equalize the movements. The *weakest parts* of the column, and consequently the parts most liable to injury, are at the junctions of flexible to comparatively inflexible portions of the column. Hence, these parts are; the dorso-lumbar; the cervico-dorsal; the atlo-axial, regions.

The various kinds of injury and disease including malformation, to which the spine is liable, may be conveniently arranged in order as follow;

(1) Wounds, involving the cord; (2) Sprain; (3) Fracture, and Dislocation; (4) Concussion; (5) Compression; (6) Caries; (7) Lateral Curvature; (8) Spina Bifida.

**INJURIES.**—WOUNDS, like other injuries, of the spine, owe their importance to the probability or certainty, as the case may be, of the cord being involved, primarily by the lesion itself, or secondarily by its inflammatory consequences.

The *causes* of any such wound are; stabs with pointed instruments, as by a sword thrust, or with a knife or fork; gunshot injury; fracture of the spine, implicating the cord, by pressure of a displaced fragment. This latter cause of wound is associated with compression of the cord, and is the most common form of that injury.

Certain *symptoms*—those of paralysis, motor, sensory, or both, are common to a wound of the spinal cord, in any part of its extent; unless above the origin of the phrenic nerve, opposite to or above the third cervical vertebra, when death is instantaneous from paralysis of the diaphragm and other respiratory muscles, causing immediate asphyxia. But the symptoms of paralysis vary according to the *region* in which the cord is wounded,—as in the cervical region, below the origin of the phrenic nerve, the dorsal, or the lumbar regions; and the corresponding symptoms, which indicate these injuries of the spinal cord, are fully described in connexion with Fracture of the Spine.

**SPRAINS.**—The ligaments connecting the vertebræ, together with the muscles which lie in the vertebral groove on either side of the spinous processes, are liable to be overstretched and torn, sprained, or ruptured. Any such lesion will be more or less localized, according to the rigidity of the part injured, as in the dorsal region, or its elasticity, as in the cervical or dorsal regions,—where, the force being broken and distributed, the sprain will be more general.

The *symptoms* are, sudden and acute pain in the part affected, which is elicited by pressure, or by any movement involving that part of the spine. The patient, therefore, lies in the position which ensures rest. Swelling and ecchymosis, may be well marked or scarcely perceptible; and the discoloration may not ensue for some days after the injury. The *diagnosis* from fracture of the spine will be determined by the absence of any displacement in the vertebræ, the line of the spinous processes being straight, and their points level. The pain on pressure is not limited to the processes of one or two vertebræ, as in fracture; and the patient can erect the spine, though with painful difficulty, but without presenting any deformity. The symptoms of sprain continue for a longer or shorter period; a bad sprain in the loins lasting, perhaps, for a month or six weeks. Voluntary movement is gradually attempted as the pain induced passes off, and this will be the surest sign of progressive recovery.

The *causes* of spinal sprain are generally such occasions of violence as bend the column downwards and forwards, with a sudden and excessive depression. The force may be external, as by a heavy weight falling on the back when the lower limbs or the pelvis is fixed; the dorsal spine then acting as a long lever, the junction of its base with the pelvis being the fulcrum, and the superincumbent weight of the trunk representing the force, forwards. The lumbar spine is thus sprained. A similar effect may be produced by the weight of the trunk itself, as when a person falls or jumps from a height, and alights on his nates. The to-and-fro twisting of the spine resulting from a railway collision, may produce the most

severe sprain. Violent muscular efforts may sprain some part of the spine, as in the endeavour to lift a heavy weight, or in pulling; or by a sudden wrench in the act of starting forward from impending danger.

*Complications, and Consequences.*—Sprain in the lumbar region is not unfrequently complicated by *hæmaturia*, blood passing with the urine, for several days after the accident. This arises from some lesion of one or both kidneys, owing to their contiguity to the lumbar spine. The quantity of blood lost varies. Generally, the urine has a deep red or brown colour, only for one or two days; it may become clear and florid on the third or fourth day; and, in a day or two more, the urine may resume its natural appearance. Clots sometimes form in the bladder. Nephritis,—inflammation of the kidney, rarely ensues, as a consequence of this traumatic hæmaturia; an immunity in connexion with injuries of the spine, which is unexceptional in the experience of Mr. Le Gros Clark. Previous disease of the kidneys will predispose to hæmaturia from comparatively slight injury to the lumbar spine; as when associated with renal calculus, or with the congestive, early, stage of albuminuria.

*Hæmorrhage into the vertebral canal*, with compression of the cord, and paralysis, is an occasional complication of spinal sprain. It will always be difficult or impossible to determine by appropriate symptoms, whether the intra-vertebral hæmorrhage be situated outside or inside the theca of the cord, and hence the source of the extravasated blood. Post-mortem examinations of clinically observed cases are wanting, to complete the solution of this interesting question.

*Inflammation of Joints of the Spine.*—A serious consequence of sprain of the spine is inflammation of the articulations; extending perhaps to the membranes of the cord, as spinal meningitis, or even involving the cord, spinal myelitis. Suppuration within the vertebral canal may ensue, and thence compression of the cord. But, the loose connexion of the fibrous theca or dura mater within the canal, which has a distinct periosteum,—unlike the adherent dura mater within the cranium, which serves the purpose of periosteum, is an anatomical condition unfavourable to the extension of the articulatory inflammation of the spine. The violence of the sprain is certainly no measure of the probability of inflammation supervening; comparatively slight injury having perhaps this consequence, while severe sprain may not be followed by inflammation.

The *symptoms* are those of paralysis, the inflammation being of a chronic character and leading to suppuration. In an early stage, the paralysis may be partial, depending on the compression of some of the spinal nerves, as they issue through the inter-vertebral foramina; in a later stage, the paralysis may become more general, from intrusion of the abscess into the vertebral canal, and compression of the cord, resulting in complete paraplegia. At this stage, chronic abscess around and within the vertebral canal, as the consequence of spinal sprain, might be mistaken for caries, with abscess and destruction of the bodies of the vertebræ. But the absence of angular deformity at the seat of disease by the upper portion of the column inclining forward, will probably determine the question of diagnosis. Spinal abscess from sprain may terminate by resolution with the removal of compression, and restoration of the functions of the cord; leaving perhaps the diseased articulations in a state of ankylosis. Or, the abscess breaks, and continuing to discharge pus, the prognosis is unfavourable.

*TREATMENT.*—Uncomplicated sprain of the spine should be treated on

the principles which relate to sprains of the joints generally:—(1) Perfect rest of the body, in the recumbent position, or on a prone couch; (2) Fomentations, warm and sedative, as by a decoction of poppy-heads, or a lotion of lead and opium; subsequently, stimulating applications, as camphor liniment, or the tincture of iodine; (3) Mercurials, as the bi-chloride, in small and continued doses, with bark, and good nourishment. Some sort of stay support may be requisite when the patient begins to get about.

The complications and consequences of spinal sprain must be treated as explained in connexion with Hæmaturia, and Compression of the spinal cord from intra-vertebral hæmorrhage or suppuration.

**FRACTURES OF THE SPINE.**—*Structural Conditions.*—The several parts of each vertebra are liable to fracture. The processes, articular, transverse, and spinous, may severally be the seat of fracture; and in particular, the spinous process. The arch is sometimes fractured on either side of this process; and the body of the vertebra is liable to fracture obliquely. The ligaments corresponding to these several portions of bone are ruptured with fracture, more or less completely. In fracture of the body, the anterior and posterior common longitudinal ligaments are torn through. Displacement will depend on the extent of fracture, and on whether the force producing it be direct or indirect. Thus, fracture of the body of a vertebra, and by indirect violence, as a fall on the head from a height, will occasion great displacement; the upper portion of the body being driven downward and inwards, and the lower backwards and upwards, with excurvation of the spine posteriorly. (Fig. 380.) Direct violence of an extreme kind will also produce displacement; as a gunshot injury to the spine.

FIG. 380.

*Dislocation* may accompany spinal fracture; and dislocation of the articular processes in the back and loins cannot, perhaps, occur without fracture. In the neck, these two forms of injury may occur independently. This difference is owing to the different direction of these processes in the three regions of the spine; in the cervical region being oblique and approaching a horizontal direction; while in the dorsal and lumbar regions, they are vertical.

The spinal cord and its membranes suffer compression or laceration, in fracture with displacement of the bodies of the vertebræ (see Fig. 380); but the membranes are comparatively rarely ruptured or torn.

Arterial hæmorrhage in the substance of the cord is inconsiderable; the vessels permeating the cord being minute and soon ceasing to bleed. Venous blood, from the large sinuses in the vertebral canal, collects in perhaps considerable quantity between the vertebræ and the dura mater; and particularly under the arches of the vertebræ where the attachment of this membrane is loosest.

*Symptoms.*—The symptoms of spinal fracture are both general and special or pertaining to the particular region which may be the seat of fracture.

The *general* symptoms are locally some alteration of contour in the line of the spinous processes, depending on and proportionate to the *displacement*. The processes above the seat of fracture are depressed, and correspondingly prominent below. The transverse processes also may have become prominent, and the spine twisted on itself. Rarely can any mobility or crepitation be felt, unless the fracture be limited to one or other of these processes. Pain is experienced at the seat of injury, and there is a notable inability to support the trunk erect. The general symptoms otherwise refer to injury of the *spinal cord*, itself also dependent on the displacement. The functions of the cord are more or less completely suspended or destroyed. Thence, paralysis of sensation and voluntary motion below the seat of fracture; involuntary evacuation of the *fæces*, which become blackish, pultaceous, and have an offensive odour, and retention of urine, which becomes ammoniacal, and voided by a dribbling incontinence. Such are the regular symptoms. Priapism and emission of the semen may occur as occasional symptoms.

Fracture in the upper part of the *lumbar* region, produces also a tympanitic condition of the abdomen; the intestines being almost suddenly distended with gas. In the upper part of the *dorsal* region, the thoracic respiration is embarrassed or suppressed, by compression of the cord above the origins of the intercostal nerves. At the *sixth cervical* vertebra fracture is attended with paralysis of the upper extremities; and above the *third cervical* vertebra, compression of the cord will be instantly fatal by asphyxia—the phrenic nerves thus being paralysed.

*Causes.*—External violence applied directly, or indirectly, to the vertebral column, represents the two modes of fracture-production. A blow or fall, on the back, is one mode of fracture; a fall on the top of the head, or compression of the trunk vertically, as between the box of a carriage and an archway, is the other, or indirect mode of producing fracture of the spine.

Extravasation of venous blood in the vertebral canal, between the vertebræ and dura mater membrane, has already been noticed; but its pathological operation is significant, as being an additional source of any pressure on the cord arising from displacement *with* the fracture.

*Course and Termination.*—Inflammation with effusion, may be a further occasion of pressure, at a subsequent period. Bed-sores are extremely liable to form over the sacrum or other prominent points, when subject only to the pressure of a water-bed; the vitality of the skin declining in consequence of the paralytic condition. A chronic inflammatory state of the bladder, with mucous or muco-purulent, and ammoniacal urine, supervenes; and even sloughing of the bladder, with extravasation of urine, I have known to occur. Increasing exhaustion accompanies the paralysis, and death ensues.

But the *period* of fatal termination which thus takes place in most cases, varies according to the situation of fracture, the degree of displacement also, and pressure on the cord. Above the third cervical vertebra, death may not occur immediately, unless the fracture be attended with displacement. Between the fourth cervical and the first dorsal, fracture is not generally fatal, under from three to ten days. With fracture in the dorsal region, the patient may live from two to three weeks. With fracture in the lumbar region, life may be prolonged from three weeks to two months, or possibly, many months.

*Treatment.*—The fracture itself cannot be treated. No displacement

of consequence, can well or safely be rectified; and no mechanical appliances can be applied effectually. Any injury to the spinal cord must be treated with reference to inflammation. The patient being placed in bed, flat on his back, to ensure rest; local depletion by leeches may first be employed, followed by counter-irritation, cautiously, having regard to the tendency to bed-sores. Subsequently, the administration of strychnine in small and increasing doses, continued until slight tetanic twitchings are produced, will have the most beneficial influence on the paralysis. *Trephining* the spine, was proposed by Mr. Henry Cline, and actually performed by him in one case, and by Mr. Tyrrell in another. Both were fatal. And this practice is properly condemned by Liston and Lawrence.

The state of the bladder will require the constant introduction of a catheter to relieve retention; while the treatment appropriate for chronic cystitis may have some avail in changing the character of the urine. Bed-sores must be prevented, if possible; or treated, by a proper adjustment of ring-cushions or air-pillows, and a water-bed is often a critically important resource.

CONCUSSION OF THE SPINAL CORD.—This expression is used to denote a shock, shake, or jar, of the spinal cord, as the immediate effect of violence, directly or indirectly applied to the Spine. This is attended with or followed by an impairment or loss of functions depending on the integrity of the cord—symptoms of a paralytic character.

The *pathology* of injury referable to concussion of the spinal cord, has been, and is still, disputed. It is argued, that the peculiar anatomical construction of the spine, and the condition of the enclosed cord—the elastic and graduated flexibility of the one, and the loose, isolated state of the other, suspended in a tubular investment of sub-arachnoid fluid; are circumstances which render it highly improbable, if not impossible, that vibrations of force should be communicated to the cord. All these circumstances are of an opposite character in relation to the brain, which is subject to concussion from injury to the head. On the other hand, injury of the spine, accompanied with paralytic symptoms, is not unfrequently met with; in which, upon examination during life, or after death, no fracture, displacement, extravasation of blood, or other cause of compression, can be discovered. Injury of this kind, distinguished by the absence of any perceptible structural alteration, is referred to concussion of the cord, in explanation of the peculiar functional symptoms. And analogy would seem to confirm this interpretation of the symptoms produced, although the intimate nature of the change in the concussed or shaken nervous structure cannot be demonstrated. We do not know—observes Mr. Erichsen—how it is that when a magnet is struck a heavy blow with a hammer, the magnetic force is jarred, shaken, or concussed out of the horse-shoe. But we know that it is so, and that the iron has lost its magnetic power. So, if the spine is badly jarred, shaken, or concussed by a blow or shock of any kind communicated to the body, we find that the nervous force is to a certain extent shaken out of the man, and that he has in some way lost nervous power.

The *secondary* changes of structure which the spinal cord undergoes are those of inflammation, of a chronic character; and as affecting the membranes—chronic Spinal meningitis, and the cord—chronic Spinal myelitis; the former usually extending to, or being accompanied with a similar affection of the cerebral meninges—chronic Cerebral meningitis.

In *Spinal Meningitis*, the structural changes consist ; of increased vascularity of the membranes, the meningo-rachidian veins being engorged, and the vessels of the pia-mater injected, in patches or uniformly ; serous fluid, reddish and clear, or opaque from the admixture of lymph, is effused, more or less in quantity, within the arachnoid, or there may be adhesion of its visceral and parietal surfaces, and puriform lymph in the sub-arachnoid space. In *Spinal Myelitis*—the inflammation affecting the substance of the cord, this undergoes softening, and atrophy—the whole of the nervous substance even disappearing, and leaving nothing but connective tissue at the part affected. The extent of this structural change varies ; the whole thickness of the cord may be affected at one point, or one of the lateral halves in a vertical direction, or it may be limited to the anterior or posterior aspect ; or restricted principally to the central gray portion, rather than the circumferential part of the cord. When myelitis is consecutive to meningitis, the inflammatory softening may—according to Ollivier's observations—be limited to the white substance. Such change of structure may have taken place in one region only ; in the lumbar portion of the cord, most frequently ; in the cervical, next in order of frequency ; in the dorsal, less commonly. The whole length of the cord is very rarely affected. Induration, with hypertrophy, of the nervous-substance of the cord—which resembles boiled white of egg, instead of softening and atrophy, may be the result of chronic myelitis ; as in the case of Count de Lordat, and similar cases are related by Portal, Ollivier, and Abercrombie.

Spinal Meningitis and Myelitis occasionally exist separately, either without the other ; more commonly they co-exist, but associated in very different degrees.

As the result of *railway collision*, only one case of post-mortem examination is recorded, where death ensued from the secondary and remote effects of Concussion of the spinal cord ; and whereby the symptoms observed during life were shown to be dependent on the pathological changes of structure, which, in the history of this one completed case, are presumed to exist in other similar cases. The patient was under the care of Mr. Gore, of Bath, who, however, did not see him until about a year after the accident, and then at intervals up to the time of death. The cord was carefully examined by Dr. Lockhart Clarke ; and the case is referred to by Mr. Erichsen in his "Railway Injuries," Mr. Le Gros Clark in his Lectures at the College of Surgeons, and by Mr. Shaw, in Holmes's Surgery. The case was that of a man, middle-aged, of active business habits ; who having been in a railway collision, and, without any sign of external injury—wound, bruise, fracture or dislocation, began to manifest the usual nervous symptoms. He gradually, but very slowly, became partially paralysed in the lower extremities, and died three years and a half after the accident. Post-mortem examination of the spinal cord disclosed the inflammatory congestion of the meninges, effusion, softening and atrophy, already described. More recently, a minute examination of the structural changes consequent on concussion of the cord, was made by Dr. H. Charlton Bastion. A man fell from the top of a hayrick, and had partial paraplegia, motory, but not sensory. He lived six months. Post-mortem examination showed that the medulla oblongata and spinal cord had undergone extensive granular degeneration. The important practical fact was, that in conjunction with such disorganization, the patient gradually recovered some power of voluntary motion in his limbs, and that

sensation remained unimpaired to the last. This case is reported in the *Med.-Chir. Trans.*, vol. 1.

*Symptoms.*—Concussion of the Spinal cord is attended with, or followed by, symptoms of a paralytic character, which are essentially the same in all cases; but which vary in degree, according to the direct or indirect force of the concussion, and still more in proportion to the severity or comparatively slight intensity of the injury.

(a) *Direct and severe* concussion is attended with immediate and marked symptoms. Pain at the seat of injury is felt, with loss of power in the extremities below that part, and there may be relaxation of the sphincters, the fæces and urine perhaps escaping involuntarily; and all these symptoms being accompanied with those of general Shock to the nervous system. The symptoms may pass off in the course of a few days, or result in complete paraplegia, of some months' duration or permanently irrecoverable.

(b) *Direct, but slight* concussion, is followed by similar symptoms, developed slowly and insidiously, in the course of several weeks or months; so that the causative relation between that comparatively slight injury and these apparently independent and serious symptoms subsequently, may seem improbable to the patient and to those who are unacquainted with such cases, and may be overlooked by the Surgeon. The symptoms referred to, and the order of their development, will be more particularly described in connexion with the next mode of spinal concussion.

(c) *Indirect concussion, from a general Shock to the nervous system* or of the whole body.—Railway collision usually causes this mode of concussion; the carriage being brought suddenly to a stop, the traveller's body is carried forward by its own momentum, and dashed forwards against the opposite side of the carriage, thence perhaps to rebound back again. Or, without any contact from collision, the body may receive the shock, and the trunk be thrown backwards and forwards with a considerable concussion, thus also wrenching and twisting the spine to and fro in the nature of a sprain. A fall or jump from a height, the individual alighting on his feet, or his nates, may have a similar effect; general concussion involving the cord, and spinal sprain.

The *symptoms* arising from this mode of concussion, are often slow and insidious in their progress, weeks or months elapsing ere they assume a marked intensity. They relate to the brain, the spinal cord, and the limbs.

Immediately after a railway collision an individual may suffer no apparent injury, beyond feeling generally shaken, and somewhat faint or confused: and this disturbance may soon pass off, leaving the person himself again, able to assist his seemingly less fortunate fellow-travellers, and having thus occupied himself for some hours, he proceeds on his journey. From that time, however, a general failure of nervous power ensues, the sufferer feels that the spring and the go has been taken out of him, bodily and mentally; he looks pallid, dejected and older, broken in general health—a change which is more obvious in a person of previously active habits. His friends remark, and he feels, that “he is not the man he was.” Trying, perhaps, from time to time, to resume his avocations, he is compelled to lay by, and with rest, getting better, he tries again, only to fail, until he is at length fairly knocked up. But some weeks or even months may elapse before more definite symptoms become developed. They correspond, it may be presumed, with the second stage; that wherein

the primary effects of general concussion are succeeded by the symptoms of chronic inflammation of the membranes, and of the substance of the spinal cord, with similar affection of the brain. Mr. Erichsen has carefully analyzed the symptoms presented, of which the following is a summary; premising that while all the symptoms may be manifested in the same case, they are not necessarily associated.

*Cerebral symptoms.*—With a pallid, careworn *expression*, usually presented; *pain*, giddiness, or some uneasy sensation in the head, is complained of, or may be elicited by pressure on the crown, and rotation of the head or movement backwards and forwards. The functions of the brain are defective or perverted. The *memory* is deficient as with regard to dates, words, figures. The *thoughts* are confused, the patient being unable to combine his thoughts in argument or reading, so that the latter effort is abandoned after a few minutes' attempt to read a book or paper. As a consequence of this impairment of memory, and inability to concentrate ideas, all business aptitude is lost. The *temper* undergoes some change for the worse, a calm and cheerful disposition often becoming peevish and desponding. *Sleep* is exchanged for wakefulness, or disturbed by horrible and startling dreams. The *special senses* are variously impaired or perverted. *Vision* is defective, in regard to focal distance, and clearness, so that letters of print or writing run into each other. Double vision and squint, are occasionally met with. Intolerance of light is often complained of; and black spots, or flashes of light, are constantly seen. One or both eyes may be affected. *Hearing* may be over sensitive or dull; in the former state any sudden noise startles and distresses the patient. *Taste* and *smell* are more rarely affected or perverted. *Speech* also generally remains unaffected; but stammering or mumbling occurs in some cases. *Touch* is often impaired, the patient being unable to pick up a pin, or button his dress; and the sense of weight is lost, a shilling or a sovereign on the point of the finger feeling of equal weight.

*Spinal symptoms.*—The *attitude* referable to the state of the spine is peculiarly erect and stiff, in consequence of the pain occasioned by flexion forwards, backwards, or sideways, or by any attempt to rotate the trunk. This pain restrains any movement involving the spine, as stooping, or rising from the recumbent position. The pain is elicited on examination of the spine, by pressure or percussion, in the course of the spinous processes, or by application of a hot sponge. At some one, two, or three points, sensibility will be found increased. These are commonly the mid-dorsal, the dorso-lumbar, and the cervical regions, extending over two or three vertebræ. Sometimes the pain extends laterally, on either side of the spine, apparently corresponding to the posterior branches of the spinal nerves. Thence the pain is musculo-cutaneous, as well as deep-seated in the spine. A distressing sensation, as if a tight cord were round the waist, with hiccuppy breathing, is sometimes experienced.

*The Limbs.*—The *gait* of the patient is very characteristic; a straddling, shambling, and tottering walk, as if his legs were not his own. Exercise, therefore, becomes more and more limited; and movement up and down stairs difficult, especially the latter act. A stick is often had recourse to habitually, or the patient steadies himself by laying hold of any support in his way. This loose gait, and rigid spinal attitude, the patient, with head erect, looking straight forwards, presents the appearance of a man walking blindfolded. The *failure of nervous power* in the limbs is very variable in its extent and degree. It may affect one or both

legs, or the arm and leg on the same side, or one arm and both legs, or all four limbs may be more or less paralysed. Motor power only, or sensation only, or both, may be lost, and in an equal or different degrees. Paralysis is seldom complete. Partial paralysis is met with; as in the extensor of the great toe, the flexors of the fingers, or the muscles of the ball of the thumb. Motor paralysis may be tested by the galvanic current, so as to excite the irritability of the same muscles in the opposite limbs. Loss of motor power in the hand can be estimated by the force of the patient's grasp, or more delicately by the dynamometer. The sphincters are rarely affected; frequent micturition being met with occasionally, retention of urine seldom, and involuntary defæcation perhaps never. Diminution or perversion of sensation; comprises numbness, as shown by Brown-Séquard's instrument; coldness, perceptible to the touch, or shown by the thermometer; and various sensations of tingling, like pins and needles, burning and darting sensations. These feelings are often limited to a single nerve, as the ulnar or the musculo-spiral. Sexual desire and power are generally greatly impaired, or even entirely lost.

*Nutrition* fails, the muscles becoming wasted, and soft in some cases, with a diminution in the size of the limbs as shown by measurement; but a contracted and rigid state of certain muscles supervenes in some advanced cases, as affecting the deltoid, the little and ring fingers, the muscles of the calf, or the extensors of the great toe,—these muscular affections contrasting with the softened state of the muscles in general. The *pulse* varies in its character at different periods. At an early period it is usually slow; at a later and advanced period, it is quick, rising to 90 or 100. It is always feeble. This state of the pulse, especially its increased and increasing rapidity, is always a significant symptom.

*Diagnosis.*—Concussion of the spinal cord must be distinguished from other injuries and diseases. From *spinal sprain*, concussion differs in the presence of paralytic symptoms; unless the sprain be complicated by intra-vertebral hæmorrhage, or intra-vertebral suppuration as a consequence of inflammation, in either case causing compression of the cord. *Cerebral Concussion* is difficult to distinguish from concussion of the cord, the two being usually associated; and the precise diagnosis is unimportant. But the pain in parts of the spine, and its rigidity, are differential symptoms as to the seat of injury. From *rheumatism*, concussion of the cord differs in the presence of true paralytic symptoms, motor, sensory or both, and the localized spinal pain; the progressive character of the symptoms, and the previous history of the case, as commencing from injury. The concomitant articular inflammation, and state of the urine, in regard to lithic acid and the deposit of lithates, are, on the other hand, symptomatic of rheumatism. *Hysteria* as manifested through the spinal cord by hysterical paralysis, may simulate paralysis arising from concussion of the cord. But the history of the case, its progressive character also, and without any complete intermission of the symptoms, are clearly diagnostic; while, the sex, age, and temperament, of the patient, with the absence of other hysterical symptoms, may further contrast with hysteria; which commonly occurs in females rather than males, in the young rather than in the middle-aged and old, in those of an excitable and emotional disposition rather than in the steady-going, working man of business, and in whom there are no other symptoms of hysterical affection.

*Terminations, and Prognosis.*—*Death* ensues from concussion of the spinal

cord, in *most* cases, the issue of which has been known. The *period* of the fatal result,—or the probable duration of life,—varies according to the severity of the injury. *Severe* and *direct* concussion of the cord, as from a heavy blow on the back, will probably have a speedily fatal termination; and the more so if accompanied with intra-vertebral hæmorrhage. *Indirect*, and perhaps severe concussion, as from Railway collision, in most cases, which is commonly followed by paralytic symptoms slowly and progressively developed, terminates fatally in a period varying from two and a half to five years; or perhaps at a much later period,—fifteen or twenty years. When death does not ensue, *recovery* may take place, more or less completely, according to the stage of the case after concussion of the cord. The primary, and almost immediate, paralytic symptoms may pass off, and the more probably in proportion to their immediate severity, especially if the patient be young and healthy; recovery taking place completely and permanently. A period of six months, under treatment, will probably suffice to entirely reinstate the health. The *secondary*, and subsequent paralysis, from softening of the cord, consequent on Meningo-myelitis, may result in partial recovery; but complete restoration from this structural change is impossible.

The *Prognosis* of concussion of the spinal cord, must be regulated by the foregoing considerations.

I have entered more fully into the nature of this injury of the cord, on account of its great practical importance, and as being a subject of frequent Medico-legal inquiry; in not a few cases of which I have been engaged.

*Treatment*.—Rest, absolute rest, is essential to any probability of recovery of spinal concussion, or wrench. The patient should keep the recumbent position, or a prone couch may be used, until the paralytic symptoms have disappeared; and especially until the limbs have regained the power of voluntary motion, and sensibility. A prone couch offers the advantages of preventing venous congestion, affecting the spine, as the result of long-continued recumbency; any tendency to sloughing from pressure over the sacrum and nates, the liability to which is always greater in paraplegia, will also be prevented; and the prone position readily allows of any local treatment. Rest of the brain is equally essential to recovery; freedom from the excitement of business or pleasure, which although apparently beneficial for a time, is permanently conducive to a fatal issue. *Local* treatment consists, in derivation from the spinal cord, by means of dry-cupping along the spine on either side; followed by counter-irritation, by blisters, setons, issues, or even by the actual cautery, in the form of the moxa. *Constitutional* treatment comprises, the continued administration of gentle mercurials, especially the bichloride, or iodide of potassium, with quinine, as a tonic. Subsequently, when all inflammatory action has subsided, and paralysis of motion, sensation, or both, alone remains, with a cachectic state of the health; strychnine and iron, will prove efficacious. A sixteenth or twelfth of a grain of strychnine, with three or four grains of the sulphate or phosphate of iron, in the form of a pill, three times a day; may be continued with advantage until slight tetanic twitchings are induced. In conjunction with strychnine, the galvanic current should be employed; one pole of the battery being placed in the course of the spine, while the other is applied up and down the paralytic limbs, so as to excite the action of different sets of muscles. Salt-water douches, and frictions, may also have some beneficial influence. The general health and strength must be supported and renovated by a

nourishing diet, and other hygienic measures. I have seen the best remedial results from this course of treatment, in many cases.

COMPRESSION OF THE SPINAL CORD.—This injury to the cord may depend on either of three causes, or perhaps their concurrent action; intra-vertebral hæmorrhage; intra-vertebral suppuration or abscess; and fracture of the spine, with displacement. The two former causes of compression, must severally be treated on general principles; the latter is noticed under fracture of the spine. Obviously, however, no source of compression affecting the spinal cord, can be readily amenable to treatment.

DISEASE OF THE SPINE.—*Structural Conditions*.—The generic term, disease of the spine, as ordinarily understood, signifies *caries* of the vertebræ, apparently of a scrofulous character; commencing probably in the *bodies* of these bones and involving the inter-vertebral fibro-cartilages. This disease is situated, usually, in the bodies of the *mid-dorsal* vertebræ; but extending upwards and downwards to several vertebræ, the upper or lower dorsal, or even the upper lumbar vertebræ and fibro-cartilages, may be diseased. The bodies of the affected vertebræ becoming disintegrated, and the cartilages destroyed, the spine yields under the superincumbent weight of the trunk, and gradually bending forwards forms an “angular curvature,” commonly known as “hump-back;” presenting a prominence of the spinous processes of the vertebræ posteriorly at the seat of curvature.

The *spinal column* occupying the middle line of the body and being equally balanced laterally, it bends forward in that line without lateral deviation. Some such inclination is apt to take place, to one side or the other, only in the dorso-lumbar and lumbar regions, where the spine has the greatest latitude of motion. At first also, the degree of angular deformity backwards and forwards, corresponds to and represents the amount of destruction of the bodies of the vertebræ. But the human figure—unlike the permanent direction of an inclining column of brick-work, or other dead weight, yielding in the middle—has some compensatory power of gradually restoring itself to the perpendicular; thereby correcting any irregularity in the line of gravity. The spinal column is, in fact, a flexible pillar of support, and subject to the action of muscles. Accordingly, as Mr. Shaw observes—a person with angular curvature of recent occurrence and tending, therefore, to tumble head foremost—gradually regains the line of gravity. Habitually throwing the head and shoulders backward, he walks with an apparent air of pride; the angular excurvation ultimately becomes combined with two incurvations, one above, and the other below, in contrary directions; the whole spine assuming an appearance, in profile, not unlike a double bracket ( { ). If angular curvature takes place at the very base of the spinal column, allowing the whole trunk to incline forward, any such restoration of equilibrium will be impossible; and the patient gropes along with the body horizontal to the legs. The *thorax* falling down, with the spine above the point of curvature, becomes shut up as it were; the ribs being compressed, and the sternum projecting, or sometimes bent at an obtuse angle as a sort of counterpoise to the posterior protuberance. The shape of the thorax is altered, its antero-posterior diameter being increased and the vertical decreased. This shortening of the trunk gives a pot-bellied appearance to the abdomen; the whole trunk seeming to have fallen down in a lump. The viscera, thoracic and abdominal, also undergo compression; but accommodating themselves to their respective

cavities, they do not suffer apparently in their structure or functions. The aorta still following the course of the spine, bends with it at the seat of curvature. Rarely is the spinal cord compressed or otherwise injured; sometimes, it becomes softened at the angle of curvature and paralysis of the parts supplied below ensues.

*Signs and Symptoms; and Diagnosis.*—Disease of the spine commences with a sense of weakness in the back, the patient feels some inability to stand upright, and leaning forwards, rests his hands on his knees, or avails himself of any other temporary support. This sign is never absent, and it is rendered equivocal only by its connexion also with hysteria affecting the spine. A slight *prominence* soon appears in some portion of the spine, usually in the dorsal region, and this point is tender or painful when pressed or tapped with the fingers; the patient wincing when pressure falls on it in examining the line of the spinal column. But pain is a very inexact symptom. It may be entirely absent with marked angular deformity, and present, severely and persistently, in a particular spot without spinal disease, as in some cases of hysteria. *Rigidity* of the spine is an equally early and exact sign with falling weakness and angular deformity. It is readily perceived by desiring the patient to stoop and raise himself alternately, or by then placing the hand on the suspected vertebræ; the spinous processes may be seen and felt to move unitedly as a connected mass. This loss of separate mobility is said to arise from the adhesive solidification around the arches of the vertebræ, forming a compensatory support, while the bodies are destroyed by carious disintegration. Symptoms referable to the *spinal cord* supervene; shooting pains extend round the trunk or down the limbs; and the patient has a tottering, sprawling gait, with spasmodic affections of the muscles of the lower extremities, or relaxation of the sphincter ani and retention of urine, or other paralytic symptoms. The angular deformity of the spine has now become well marked, and is rendered more conspicuous by wasting of the muscles in the trough on either side of the spinal column. The excurved ridge of ~~transverse~~ processes stands out like a keel, with a serrated edge, the tubercle of each process being distinctly visible. The transverse and oblique processes, also, become distinguishable.

Pus forms in connexion with caries of the vertebræ; at a more or less early period, and more or less abundantly, in proportion to the tuberculous character of the disease. The pain and paralytic symptoms—referable to the spinal cord, are relieved for a while, by suppuration. But it is only as a presenting abscess, that the formation of matter becomes clearly available as a symptom of disease of the spine. This event—the appearance of an abscess, will depend on the progress of spinal disease, as described in connexion with its *course*.

*Causes.*—The scrofulous constitution is probably always predominantly influential as a predisposing cause, leading to a deposit of tuberculous matter in the bodies of the vertebræ, which seems to be the exciting cause of carious disintegration. Some slight injury to the spine may apparently give rise to the disease,—fixing the date to which it would appear referable.

Any period of life is liable to caries of the spine. Beyond middle life it is very rare; in childhood and adolescence, most common. It occurs equally in both sexes.

*Course and Terminations.*—*Abscess* results from the continued forma-

tion of matter. It may undergo *resolution*, the matter being slowly absorbed. In this way a large proportion of patients pass through the whole course of spinal disease, even to paraplegia, and regain their general health, without any signs of abscess in connexion with the vertebræ having appeared. A process of restoration goes on also in the vertebræ. Carious disintegration and absorption are followed by bony deposit between the bodies,—in the place of inter-vertebral fibro-cartilages, thus fusing and consolidating the bones into one mass; while bridges of bone are thrown out from body to body, forming additional buttresses of support to the spinal column. This *anchylosis* is the natural cure of disease of the spine,—a not uncommon event, especially when aided by proper treatment; the patient remaining deformed.

In a case of angular curvature, at the junction of the last dorsal and upper lumbar vertebræ, and of two years and a half duration from the symptom of falling weakness; I succeeded in inducing anchylosis by the recumbent position continued for nine weeks, when the patient had sufficiently recovered to take gentle walking exercise. After the lapse of nine months, he could walk ten miles a day, and had recently become a Hansom cab-driver,—bearing the pull of the reins without any return of the spinal disease.

*Presenting* abscess represents the unfavourable course of spinal disease, as implying the continued formation of matter and destruction of the spinal column. An abscess thence proceeding, presents or makes its appearance in a variable *period*;—early, with weakness of the spine and before any deformity; or at a later period, after months or perhaps years. It appears in various *situations*; according to which, abscesses connected with spinal disease are nominally distinguished, irrespective of the particular parts of the column whence they arise. The route of any such abscess, “by translation,” is often very devious and extensive.

*Psoas abscess* is the most common, and typical. The matter arising from the dorsal or lumbar vertebræ, enters the sheath and substance of the psoas muscle,—passing in the former case through the diaphragm near the ligamentum arcuatum. Following the line of the muscle, the matter descends obliquely outwards, and passing under Poupart's ligament, appears in the groin; where by extending upon the thigh it may burrow to the knee, as a large and increasing femoral abscess. A *double* psoas abscess forms occasionally; the collection of matter at the spine, bifurcating, and passing down within the sheaths of both psoas muscles, emerges in the thighs simultaneously.

The *symptoms* of psoas abscess, as regards its connexion with disease of the spine, are somewhat equivocal. The presence of an abscess may be detected in the groin, or even in the iliac region, by the usual symptoms;—a fluid and fluctuating swelling, which is partially emptied of its contents when the patient lies in the recumbent position, and which yields a fluctuation to and fro on careful palpation with one hand placed over the iliac fossa and the other over the swelling in the groin. The communicating channel—under Poupart's ligament—may contract, whereby the abscess in the thigh becomes circumscribed and isolated; as if it were a distinct chronic abscess, connected with diseased femur, instead of proceeding from the spine.

*Diagnosis.*—The *origin* of abscess in the groin is various. It may proceed:—(1) from bubo or glandular abscess; (2) from disease of the hip-joint; (3) from iliac abscess, connected with disease of the iliac bone,

or forming in the fossa; (4) from peri-cæcal abscess, on the right side only; (5) from peri-nephritic abscess; (6) from empyema, perforating the pleura and descending behind the diaphragm. The diagnosis of *abscess*, thus agreeing in situation, but differing widely in origin, will be guided by the *association of other symptoms*; the presence of other symptoms of spinal disease, or those of one of the diseases above named. Thus, with weakness and slight excurvation of the spine, abscess in the groin would indicate this disease; with the present or past association of a chancre, or of shortening of the limb on the side affected; such abscess would, respectively, denote its syphilitic origin, or refer probably to disease of the hip-joint. Compared with other tumours, in the groin or iliac fossa; abscess, in these situations, differs more or less, in its *own* characters. Thus, from *fatty tumour* in the groin, abscess differs, in its fluid and fluctuating character and partial subsidence in the recumbent position, as compared with the solid doughy consistence and irreducibility of a fatty mass. *Femoral hernia* is distinguished chiefly by the perceptible impulse on coughing, and gurgling character of the swelling.

The *progress* of psoas abscess is mostly unfavourable. Resolution of an internal abscess which has already enlarged so far as to become apparent, is a rare event. Slowly perhaps, but surely increasing, the abscess eventually bursts. The general health inevitably undergoes a great change. From a comparatively local state of disease,—the patient carrying about a large indolent abscess in his thigh, constitutional disturbance now supervenes, in perhaps a day or two, or a week or two. Hectic fever with great emaciation supervenes, large bed-sores form, and the patient dies exhausted.

**OTHER VARIETIES OF SPINAL ABSCESS.**—The different *situations* in which spinal abscess may make its *appearance* are specially worthy of notice

Psoas abscess emerges from under Poupart's ligament, in the narrow interval between the united bellies of the psoas and iliacus muscles and the anterior inferior spinous process of the ilium; its progress is arrested by the origin of the sartorius and tensor vaginæ femoris muscles, which incline it inwards obliquely across the thigh, in the line of the sartorius. But the abscess may turn abruptly inward or outward, at the groin; or coursing downwards, divide into two portions, an inner and an outer; or burrow under the muscles of the thigh, into the popliteal space, or pass thence on to the calf or ankle. Sometimes, this abscess descends into the sub-peritoneal tissue of the pelvis, and presents along the rectum at the anus, or emerges from the sciatic notch and passes down by the side of the trochanter.

*Lumbar abscess* is perhaps the next in order of frequency after psoas abscess. The matter passes directly backwards, chiefly by perforating the quadratus lumborum muscle, and presents a rounded broad flattened abscess. Its boundaries usually are; the lowest rib above, the crest of the ilium below, the sacro-lumbalis internally, and the margin of the external abdominal oblique muscle externally. This abscess frequently co-exists with psoas abscess. The matter may come from the lumbar or dorsal vertebræ, having descended from the latter.

*Dorsal abscess* sometimes forms, by the passage of matter directly backwards. Or, matter proceeding from the dorsal vertebræ, passes down under the pillars of the diaphragm along the aorta and iliac vessels, into the iliac fossa, and presents through the anterior wall of the abdomen

above Poupart's ligament; or sinking into the pelvis, it escapes through the sacro-sciatic notch, and collects in the *gluteal* region.

Disease of the cervical vertebræ, exhibits equally remarkable varieties of abscess in respect to the situations of its appearance. The matter coming forwards, it presents behind the *pharynx*, or may descend under the sterno-mastoid muscle to the side of the *neck*; occasionally, it passes down into the thorax, or into the *axilla*.

The pathology of all these varieties of abscess connected with spinal disease is essentially the same as that of psoas abscess. Any such abscess is liable to attain a considerable, even an enormous, size; it bursts, and discharges at intervals or continuously; hectic, or a typhoid type of fever supervening, and a fatal termination.

PROGNOSIS.—The *prognosis* in caries of the spine, is always precarious. A favourable prognosis has reference only to ankylosis, the patient remaining hump-backed for life. But this angular deformity and ankylosis have a concurrent relation; the remnant bodies of the vertebræ becoming united by the falling down of the column. Angular deformity, therefore, usually indicates a more satisfactory result, life being preserved; whereas, the spine remaining straight, is ominous of a fatal issue. For then, the spinal cord, is exposed; paralytic symptoms become aggravated, and abscess increasing by continued caries of the vertebræ, at length bursts, and leads almost inevitably to the overwhelming constitutional disturbance already noticed, hectic and exhaustion.

TREATMENT.—Guided by the natural mode of cure,—ankylosis, the primary indication of treatment is to bring about this result. Hence, absolute rest in the horizontal position must be observed, in order to prevent any motion affecting the vertebræ and to relieve the weight of the trunk from the spinal column. A prone couch (Fig. 381), the patient

FIG. 381.

lying on her belly, answers this purpose best. It should be constructed so as to admit of being raised to a varying angle with the floor, and thus render the position more tolerable than an absolutely horizontal posture. The prone position of the patient is preferable to the recumbent, as the angular prominence of the spine escapes compression and any tendency to congestion affecting the diseased vertebræ; both of which evils would result from a long continued resting of the patient on his back. In this way the progress of the disease may be arrested without further measures. Blisters, setons, moxæ, are sometimes useful adjuncts, as means of counter-

irritation; but they more commonly prove obnoxious by disturbing sleep, and enfeebling by giving rise to a draining discharge. Should these appliances be resorted to, the prone position will, obviously, be more convenient; as well as being otherwise advisable. This plan of treatment

FIG. 382.

having been pursued for six months, a year, or more, according to the state of the disease; some degree of freedom may be allowed to the patient by wearing an apparatus to support the trunk.

It consists of a broad pelvic band, as the basis, from which two steel rods, one on either side of the trunk, pass upwards, terminating in padded crutches for the arm-pits. A back plate is added for the direct support of the spine at the seat of curvature. (Fig. 382.)

Throughout the whole course of the disease, medical treatment should have regard to the improvement of nutrition. Hence tonics, of which iron and quinine are most efficacious, with cod-liver oil, and a generally nutritious diet, will aid the effect of rest in procuring ankylosis. Intercurrent paralytic symptoms mostly subside, when the disease thus progresses favourably; the spinal cord recovering its functional power. Small doses

of bichloride of mercury—from the twentieth to the sixteenth of a grain, may be given with advantage, as recommended by Stanley.

*Psoas abscess*, or abscess in any other situation, resulting from spinal disease, requires no special treatment. Like any other large indolent abscess, no interference is necessary, until it threatens to burst. A small valvular opening should then be made, to relieve tension without the admission of air; and closed, before the matter has ceased to flow, with a pad of lint and a strip or two of plaster. This procedure may be repeated from time to time, as occasion requires. If the carious disease of the vertebræ be arrested, matter ceases to accumulate; and the abscess contracting with each evacuation, its cavity will at length become closed.

**DISEASE OF THE ATLAS AND AXIS, AND OF THE ATLAS AND OCCIPITAL BONE.**—Caries of the first two cervical vertebræ is less liable to occur, there being less osseous substance than in other vertebræ. Disease begins in their articulations, or in the occipito-atloidean articulations; thus resembling disease of other joints. Swelling and pain, with rigidity or inability to move the head, are followed by abscess presenting behind the pharynx. A broad fluctuating swelling in this situation, extends to either side of the neck, giving the individual a remarkable appearance, grotesque if it were not distressing. Deglutition, respiration, and speech are impaired, the voice having a nasal twang; while with an anxious expression, open mouth and dribbling saliva, the head fixed and supported by both hands under the chin, the patient turns round bodily in looking at anything, and the eyes acquire a peculiar rolling range of motion. Wasting hectic may gradually reduce the sufferer; or his misery terminate suddenly by asphyxia, owing to pressure on the cord by dislocation of the atlas for-

wards, the transverse and accessory check ligaments having given way. The head falls forward, carrying with it the atlas, the odontoid process of the axis compresses the cord, and all is over.

It is said that the atlas may undergo dislocation *gradually*, and even so far forward as to bisect the vertebral canal into equal parts, thus compressing the cord into half its former size, yet without paraplegia resulting. The patient may, indeed, recover, with permanent dislocation and ankylosis. Certain slight defects only will then be observable; a stiff, and somewhat contorted, neck, the chin and face advanced unnaturally, and the back of the head more in a line with the spine, while the spinous process of the axis projects conspicuously.

The *cause* of this disease would appear to be a scrofulous constitution, provoked probably by some slight strain or other injury affecting the neck. Puberty seems to be the age at which the disease commonly begins; but it occurs also in infantile or adult life.

*Treatment* must be the same in principle as that of spinal disease producing angular curvature; absolute rest by fixing the head, counter-irritation when necessary, and tonics.

#### LATERAL CURVATURE OF THE SPINE.

—*Structural condition.*—Spinal Curvature may take place laterally, to one side or the other, and with another or compensating curve to the opposite side; thus presenting a very different appearance from angular curvature forward with a sharp projection backwards. Lateral curvature usually occurs in the middle of the back—mid-dorsal region of the spine, and with its convexity towards the right side; the second curve is in the lumbar region, and its convexity towards the left. This curve arises nearly simultaneously with the first curve, constituting *double lateral curvature*. (Fig. 383.) Sometimes, four curves occur; namely, besides a dorsal and a lumbar, a cervical and a lower lumbar curve are produced, also in opposite directions. There will then be two curves to one side, and two to the other, arranged alternately; the whole spine having a quadruple undulatory form. The

effect of this double and opposite curvation, whether in one or two pairs, is to bring the weight of the trunk over the sacrum, as the base of support, and thus maintain the balance of the body. Another and a remarkable change takes place, concurrently with lateral curvature of the spine. In each such curve, the aberrant vertebræ twist or undergo rotation, to some extent; so that the anterior faces of their bodies look towards the convexity of the curve, the spinous processes towards the concavity. (Fig. 384.) A double kind of curvature—*lateral and rotatory*, is the resulting structural alteration of the vertebral column. The vertebræ themselves become somewhat compressed in their *bodies*, in the concavity of either curve; but there is no apparent disease of the osseous structure.

FIG. 383.

The *ligaments* are simply stretched and somewhat relaxed. The *ribs* conform to the direction of the dorsal curvature; being thrown outwards

FIG. 384.

and upwards on the convexity of the curve—towards the right side, and inwards and downwards, at its concavity—towards the left side. The *thorax*, therefore, bulges on the one side and is depressed on the other. The *pelvis* also, conforming to the lumbar curve; is raised, accordingly, on the side of concavity—the right, and lowered on the side of convexity—the left. Rotation, or the twist of the spine, produces peculiar changes; the thorax projecting backwards somewhat, as well as outwards and upwards, on the right side; and the pelvis backwards, as well as downwards, on the left side.

*Signs, and Diagnosis.*—The signs of lateral curvature are obvious, and correspond to the structural alterations of conformation, above described. On tracing the spinal column from above downwards, by passing the finger along the tips of the *spinous processes*; some unnatural curvature of the *dorsal* spine to the one side, may be perceived, with a compensating curvature in the *lumbar* region to the other side. And this line of undulation will be rendered more visible by marking it with a pen dipped

in ink. But—as urged by Mr. Barwell in his original treatise on lateral curvature—the degree of rotatory displacement cannot be determined by the line of the spinous processes. The tips of these processes—which, until there is considerable displacement, are the only portions of the bones we can feel—are those very parts which in rotation move most away from the side to which lateral displacement tends; thereby allowing considerable displacement of the vertebræ, while the spinous processes still lie in a straight continuous line. *Bulging of the thorax*, beneath and outside the *angle of the scapula*, is an early sign, and followed by projection of this bone—"growing out" of the bladebone, at a later period. This corresponds to and denotes, the *dorsal* curve. A posterior projection of the *innominate bone*, marked by a protuberance backward just outside the *sacro-iliac joint*, is also an early sign; and followed by lateral projection of the *hip*, altering the outline of the figure, at a later period. This corresponds to and denotes, the *lumbar* curve. The priority of a prominent shoulder or of a prominent hip, denotes a curve primarily dorsal or primarily lumbar.

The *front of the chest* presents certain opposite alterations of configuration as compared with its posterior aspect. The right side appears small and depressed, the left prominent. Slighter changes of form can be detected, and the diagnosis confirmed, by an instrument designated the "rotation-measurer."

A primarily dorsal curve presents certain varieties, depending on its causes or mode of production, and which are of practical consequence.

The *weight-bearing curve*—in Mr. Barwell's experience—is uniformly the same; it occupies the upper three-fourths of the dorsal region, and the compensatory lumbar curve commences with the lower fourth vertebra. A perpendicular line from the last cervical vertebra to the middle of the sacrum, crosses the double curve once, at the ninth dorsal vertebra. The most aberrant vertebrae are the fifth dorsal to one side, the second lumbar to the other. A well-marked *vertical rounded eminence* of muscular contraction runs upward from the back part of the ilium to the most aberrant vertebrae.

Other spinal curvatures may be noticed.

The *respiratory curve* varies with its origin; namely, some external cause restraining abdominal respiration, or some internal and pulmonary disease. This curve much resembles that produced by weight-bearing; but the vertical line of muscular development is absent, and the second curve is proportionately less. Curves of *internal* origin assume a variety of shapes; a short and sharp curve, particularly if high up, will probably be the consumptive curvature; a longer curve, high up, results probably from pleurisy; and a long curve low down, proceeds mostly from pneumonia. The situation and form of these dorsal curves, will, therefore, materially determine the diagnosis of lateral curvature, having a respiratory origin.

Both kinds of dorsal curvature—weight-bearing and respiratory, lie to the *right* side, generally; but as respiratory curves are invariably so, excepting in lung disease or the rare instance of visceral transposition, any primarily dorsal curve to the *left*, will be weight-bearing.

*Causes.*—*Age* has an immediate relation to lateral curvature of the spine; this deformity taking place mostly about the age of puberty, and in girls. It would seem that at that period of life, and in the female sex more particularly, the bust and shoulders undergo development and become more weighty, than in proportion to the supporting stability of the vertebral column and its ligamentous connexions. This naturally increased weightiness of the thorax, may be augmented by certain *occupations*, as that of nurse-girls by carrying an infant constantly on one arm. Or again, the erector muscles of the spine, in common with the whole muscular system, may be in an atonic and weakened state, relatively to the increasing weight thrown upon them by the development of the trunk; and this *muscular weakness* is more liable to occur in females as a result of the anæmia of disordered menstruation. Certain occupations which compel an habitual one-sidedness of posture, provoke lateral curvature of the spine; as writing, drawing, playing the harp, or other exercises in the course of school-training. From increasing weight of the trunk, or muscular weakness of the supporting muscles, or both causes, favoured by any occupation, conducive to the operation of either cause; lateral curvature is liable to occur.

But these accredited causes do not explain certain essential characters of this deformity; to wit, the great frequency of dorsal curvature to the *right*, and the production of *rotation*. Assuming that the right arm is heavier than the left and the right lung more capacious than the left, Mr. Barwell attributes rotation to the action of the *serratus muscle*, of this side: which muscle being more weighted and in stronger respiratory action than its opponent, acts upon the ribs as powerful levers, and thus

rotates the vertebræ to the left side. In this etiology, the sequence of events, as usually described by authorities on lateral curvature, is reversed. It is generally stated, that the spine first curves laterally, then rotates, and in this latter movement, by dragging with it the ribs, deforms the chest. The rotation-theory affirms that the ribs are primarily drawn backwards, and acting as levers, twist the vertebræ to the left, curving the dorsal spine to the right.

Both these views cannot be true, but both are entitled to consideration.

*Consequences.*—For some time, the spine retains its flexibility; so that when the cause of curvature is removed, the column regains its natural direction. Consequently, in the recumbent position, recovery temporarily takes place. At a more advanced period of the disease,—after the lapse of some years, the vertebræ become fixed; and then the deformity is persistent in whatever position the patient be placed. Yet recovery can be slowly effected by proper treatment. The general health also is now more visibly impaired; emaciation and pallidity having increased with continued declining nutrition, and there being some symptoms resulting from compression of the thoracic and abdominal organs.

FIG. 385.

*Treatment.*—Any cause in operation must be removed. Thus, any one-sided posture, connected with occupation or habit, must be corrected; and the patient allowed free motion of the body, alternated with rest in the recumbent position. The correction of posture,—in the production of lateral spinal curvature, may be brought about by an antagonistic position. This may be accomplished by using the *sloping seat* (Fig. 385). By uplifting the left side of the pelvis, when depressed by lateral curvature and a lumbar arch formed on the left side, the spine is compelled, by the law of equilibrium, to curve in the opposite direction,—to the right, for maintaining balance; and thus a corrective action is established. The results of this mode of treatment are said to have been “perfectly marvellous.” Various gymnastic exercises have been recommended, and may be of some use; but the ordinary exercise of walking and running, will probably bring both sides of the body into equal

action, and the spine naturally regain a straight direction. This result will be promoted by due attention to the improvement of the general health, on ordinary principles of treatment.

In *single lateral dorsal curvature*—unaccompanied by any compensatory curve in the lumbar region; either of the annexed forms of spinal support may be worn, with much benefit. (Fig. 386 and Fig. 387.)

In a more *advanced stage*, and as *double lateral curvature*, some other mechanical means must be had recourse to for the gradual correction of this deformity. Various contrivances are used, and still more have been constructed; some specialists in this branch of surgery seeming to vie with each other in designing the most complicated apparatus. The thorax, bulging backwards and outwards at the angle of the scapula;

and the hip or haunch, projecting backwards and outwards; both require support, equal and opposite in these directions.

FIG. 386.

FIG. 387.

The simple "oblique bandage" answers this purpose very well, so far as regards the bearings of the support. Or, a contrivance, similar in character to that used for angular curvature, may be worn, to relieve the weight of the trunk by crutch supports; whereby also the varying degrees of lateral pressure requisite, can be better *regulated* by a rack and pinion worked by a key. The primary dorsal curve may, it would seem, be "unfolded," by extending its extremities (Fig. 388); thus restoring the line of the vertebral column. Unfolding is accomplished, most effectually, by raising the upper extremity of the curve, and supporting its convexity, simultaneously, as shown in figure. Replacement of the ribs and scapula—or, of the projecting shoulder, consequent on spinal rotation, must also be accomplished; and this requirement is specially provided for, in conjunction with rectification of the double curvature, by Bigg's spinal instrument. (Fig. 389.)

FIG. 388.

*Application of the Instrument*, is thus described by Mr. Bigg, in his *Manual of Orthopraxy*. "Stand behind the patient, and, opening the pelvic band, place it firmly around the hips, in such a manner that the arms rest upon the crutches. See that the two plates press gently against the arc of each curvature, the vertebral levers having been expanded previous to placing the instrument on the patient's body. Fasten the lacing bands in front, and then gradually tighten, by means of the key which belongs to the instrument, the vertebral levers. Lastly, see that the arm-slides are at such a height as to maintain the shoulders parallel with the pelvis, and fasten the shoulder-straps. As a certain amount of irksomeness is sure to be felt on first adopting any kind of mechanical appliance, the instrument should be so worn as to gradually accustom the patient to its

restraint. This is easily done by wearing it for four hours the first day, six the next, eight on the third, and for the whole day afterwards, after which time the patient readily submits to it, and always feels greatly disinclined to part with the apparatus. Where the patient is young, restoration of the spine to its straight position becomes a perfect certainty, provided that great care is bestowed upon the adaptation of

FIG. 389.

the mechanism. The pressure requires to be slightly increased at monthly intervals, and, under no circumstances, should the mechanism be more frequently interfered with. In cases where the patient has almost accomplished her growth, it is highly desirable to keep the instrument applied by night as well as day, thus taking advantage of the slight time left for rapid improvement. In adults, great and beneficial change can be wrought in the position of even the worst form of lateral curvature, but it requires a longer time and more care in adjustment than when a younger person is being dealt with. The mechanical action of the instrument is greatly facilitated by causing the patient to

FIG. 390.

recline on a chair as is here represented (Fig. 390), for two hours daily; as by this means additional rest is given, and also the mechanical powers of the instrument are left to exercise a freer influence than when opposed by the constant reaction of the patient's weight and muscular resistance. In cases where I have tried an instrument only, and in others where recumbency has also been added, a great difference of progress, in favour of the latter course has been observed." By an instrument, similar in principle to this, I have succeeded in arresting the increase of one of the worst cases of double lateral curvature.

Pressure on the dorsal arc, *without* vertical elongation, as the principle of treatment, is represented by the accompanying form of spinal instrument,—which is much advocated and in constant use (Fig. 391).

The *reduction-couch*, of Buhring, is a means of applying the *unfolding* principle of treatment to double lateral curvature, by *recumbency*. And Dr. Bauer of Philadelphia, who highly praises this contrivance, observes that it differs from all other spinal couches, and appliances, in this special advantage; that the pads which act on the vertebral curves, rest against the transverse and spinous processes, instead of upon the lateral surface of the ribs. Compression of the thorax is thus avoided; whilst, from the

thickened shape of the pads, rotation of the vertebræ is induced. The apparatus, as described by Mr. Bigg, consists of a padded metal plate, sufficiently large to admit of the body reclining upon it. Corresponding with the position of the pelvis, a steel band is fixed which surrounds and firmly retains the hips in contact with the couch. Under the left arm an axillary pad, governed by a long screw, is placed, and it raises the concavity of the upper and dorsal curve, whilst, on the convexity of this curve and the right side of the couch, a pad softly covered and shaped like a thick wedge presses upon the transverse and spinous processes of the dorsal vertebræ. On the left side, another pad of a similar wedge-shaped form, but less in breadth and thickness, rests against the spinous and transverse lumbar processes. Both of these pads are moved by horizontal screws, so placed as to admit of the spine being pressed in an antero-lateral direction. The effect of this mechanism is shown in the adjoining sketch, which represents a patient undergoing treatment upon a Buhning couch. (Fig. 392.) It will be seen that the pads not only act upon the body laterally, but also raise the thorax upwards,—thus overcoming

FIG. 391.

FIG. 392.

rotation of the spine. As the weight of the body rests almost entirely upon the pads, an antero-lateral movement of the vertebræ takes place,—the spinal curves becoming reduced by a kind of unfolding process, peculiar to this contrivance. A loop of leather fastened to the pillow enables the patient to assist the expansion of the dorsal curve, by holding the left arm across and above the head.

Much care should be observed in the construction of this couch, so that the pads may bear strict relation in their form and thickness to the condition of rotatory-lateral curvature presented by the patient's spine; but as the pads can be easily removed by a simple arrangement in the plate attached to the screw, a very little practice soon determines with accuracy the exact size and thickness of padding required in the individual case. Dr. Bauer says that patients rapidly become accustomed to

the frequent use of this couch and derive the greatest comfort from its use, readily sleeping all night upon it.

POSTERIOR CURVATURES OF THE SPINE.—*Cyphosis* is a term intended to signify an *excurvation* of the spine in the dorsal region, presenting a remarkably *round-backed* appearance; a deformity which sometimes takes place. (Fig. 393.) The left figure shows this deformity; and an

FIG. 393.

apparatus, which, from the direction of pressure on the spine—*above* the curvature, would increase it; while, the adjoining figure represents the proper situation for spinal support,—*above* two vertebræ *below* the axis of distortion. The most notable instance I have ever seen was in the person of a Surgeon, about fifty years of age, and whose general health remained unaffected. *Lordosis* represents *incurvation* in the lumbar

FIG. 394.

region, and is of more rare occurrence. (Fig. 394.) Both these spinal curvatures appear to be simply an enlargement of the natural curvatures existing in their respective regions; they thus differ from

angular curvature, and also in being unconnected with caries or other disease of the spine.

The *Treatment* should be conducted on the same mechanical principles of counter-support or pressure, gradually applied, as in the management of lateral curvature. The apparatus for *Cyphosis* is represented in the preceding figure. (Fig. 393.) For *Lordosis*, a stay-apparatus should be worn, having upright crutch-supports to relieve the weight of the trunk, but provided with a padded back-plate, or an abdominal band (Fig. 394); the former appliance resembling the apparatus used for anchylosing angular curvature. In the two figures; that to the left shows where the axis of the curve is to be found,—as indicated by the *arrow*; that to the right, depicts the abdominal support, and joint of the upright, so placed as to correspond exactly with the centre of curvature.

SPINA BIFIDA.—*Structural conditions*.—A congenital malformation, signifying the absence or deficiency of the laminæ and spinous processes of some of the vertebræ, with protrusion of the membranes of the cord through the opening thus left in these bones. The sac, formed, contains a thin clear colourless fluid,—cerebro-spinal, which accumulates as the protrusion increases. This structural defect,—resulting from an arrest of development, may occur in any part of the spinal column; in the lumbar region, usually; in the dorsal or cervical region, rarely. The spinal cord and nerves are not generally involved; but above the lumbar region, they are liable to be adherent to the interior of the sac.

The *symptoms* of spina bifida are obvious. A round or oval tumour, varying in size from a walnut to a child's head; lobulated occasionally. Of hard, but elastic consistence, fluctuation is obscure. These characters are most marked when the infant is placed upright, softness and fluctuation becoming perceptible in the horizontal position of the trunk. The tumour subsides also somewhat on pressure, but its tension is alternately increased and diminished by expiration and inspiration.

The *course* of this malformation is uncertain, varying principally according to the size of the tumour. If the sac be small and remain stationary, it may not shorten life. A large sac generally has a fatal termination; death occurs from convulsions, or inflammation and ulceration of the integuments taking place, spinal meningitis supervenes.

*Treatment*.—This also, guided by the probable course of the tumour, will depend on its size. A small sac, with healthy integuments, is best left alone; the patient wearing a soft pad over the tumour, simply as a further protective covering. A larger-sized sac, and with the integuments in the same healthy state, may be restrained by a compress and bandage; an india-rubber air-pad affords the most uniform and elastic support. Increasing tension can be relieved by puncture as occasion requires, and pressure should then be reapplied. Extirpation has been resorted to successfully; but this procedure or indeed any operative interference for removal of the sac is always more perilous than the tumour itself.

## THE THORAX.

## CHAPTER XLIX.

## INJURIES OF THORACIC PARIETES, AND ORGANS.

INJURIES of the chest are of common occurrence in Civil Practice, while they form a very important section of Military Surgery. The grand practical distinctions of these injuries are as follow :—

WOUNDS OF THE PARIETES OF THE CHEST.—These lesions, not penetrating the thoracic cavity, present nothing peculiar in their pathology and treatment. Rest of the injured part will be best secured by means of a broad rib-bandage, thus restricting the breathing to abdominal respiration, as in the treatment of fractured ribs or sternum. This appliance must be removed if the restraint prove distressing to the patient.

INJURIES INVOLVING THE THORACIC ORGANS.—Whatever part of the thoracic parietes be injured—the ribs or sternum—and whatever internal organ be implicated—the lung, heart, or great vessels; certain symptoms are common to these injuries, coupled with special symptoms according to the situation of the injury as implicating a corresponding internal organ.

*Symptoms.*—The shock of injury is always well marked, amounting to extreme collapse.

If the *Lung* be wounded or ruptured, there is also sudden dyspnœa, with a tickling spasmodic cough and bloody-frothed expectoration, or considerable hæmoptysis of pure blood. The air inspired, escapes at the seat of pulmonary lesion, into the cavity of the pleura; constituting *pneumothorax*, with proportionate *collapse* of the lung. If the costal pleura also be wounded, the imprisoned air passes, during expiration, from the pleural cavity externally, infiltrates and distends the cellular texture, perhaps very extensively; thus constituting *emphysema*. Hæmorrhage taking place into the pleural cavity is known as *hæmothorax*. An external wound of the integument, as a penetrating wound of the thorax, presents certain distinctive symptoms; air escapes and is drawn in alternately during the act of respiration, and the lung may protrude to some extent through the thoracic aperture, forming *hernia* of the lung.

The consequences of injury to the lung may be; inflammation of that organ—*pneumonia*; and with regard to the pleura—*pleurisy*—terminating perhaps in pus-formation and its accumulation, within the pleural cavity—*Empyema*.

If the *Pericardium* or the *Heart* also, be injured; then, in addition to the extreme collapse, the only peculiar symptoms will be as connected with the pericardium; hæmorrhage taking place into its cavity, or inflammation of that membrane—pericarditis ensuing, when life is sufficiently prolonged for this event.

Different parts of the heart are liable to be wounded, and according to Ollivier's inquiries, in the following order of frequency; right ventricle, left ventricle, the apex or base, right auricle, left auricle.

Rupture of the heart occurs also in different parts of the organ, with some relative order of frequency—as shown by Gamgee's collected cases.

Of 27 instances, in at least one-half, the pericardium was entire; in 12 the rupture was on the right side, in 10 on the left. The right ventricle was ruptured in 8, the left in only 3 cases; whereas, the left auricle was torn in 7, the right in only 4 cases.

*Causes.*—*Fracture* is the most frequent form of thoracic injury in connexion with wound of the lung, the pericardium or heart; the ribs or the sternum, respectively, being the seat of fracture, and the broken ends of bone, thence driven inwards, being the immediate cause of the injury to either thoracic organ. *Contusion* or *compression* of the chest, without fracture, as by a violent blow or squeeze, may directly rupture the lung, pericardium, or heart. The latter organ has been ruptured by indirect violence; as by a fall on the head, shoulder, or lower extremities. Spasmodic contraction of the heart under the influence of great mental emotion, is also said to have caused rupture; the unhappy sufferer dying literally of a broken heart. Lastly, a *penetrating wound* of the chest, as by a stab, a bullet or other gunshot injury, may also directly implicate either organ; but this occasion of internal injury is comparatively rare in civil life.

*Prognosis.*—Wounds of the *Lung* are always perilous, but less so than similar injury of most other viscera. The cause and depth of the wound will mainly determine the prognosis. Thus, a wound produced by a fractured rib is rarely fatal, either in itself or its consequences; whereas, contusion causing rupture of the lung, is frequently more serious; and a penetrating wound is always dangerous, proportionately to its depth. Hence, a stab may soon prove fatal, although I have seen a case where the lung was penetrated by a fork, as shown by the bloody expectoration, and yet the patient soon recovered. A bullet-wound is most perilous, owing to its depth and the uncertain extent of the injury; perhaps implicating the root of the lung. More than half the cases of gunshot wounds of the chest, die. After the battle of Toulouse, of 106 such cases, nearly half died; and of 40 cases at the Hôtel Dieu, 20 died. Of 147 cases in the British Army, during the Crimean War, 120 died; and of 200 cases in the Russian Army at the siege of Sebastopol, only 3 recovered. The usual cause of death is hæmorrhage, primary or secondary. And thus, according to Hennen, death generally ensues before the third day; after which, if the patient survive, the prognosis will be favourable for recovery, subject to the contingencies of inflammation and its consequences as affecting the lung and pleura. Wound of *both* lungs simultaneously is proportionately more dangerous; and principally owing to double pneumothorax with collapse of the lungs, inducing more complete asphyxia. Recovery is however an occasional termination, even in such cases.

Wounds of the *Heart* are generally fatal, and almost immediately, from internal hæmorrhage and collapse. Sometimes, life continues for a period of some duration; the patient may have walked or run a considerable distance before falling down dead. In 29 cases, collected by Ollivier and Sanson, of penetrating wounds of the heart, forty-eight hours elapsed before death ensued. But here again, the extent of the wound, its direction, and the cavity of the organ injured, are very material prognostic considerations; when any such particulars can be ascertained during life from the mode in which the injury was inflicted. Thus, a wound in the direction of the axis of the heart is not so speedily fatal as a transverse wound; and a wound of the auricle is more immediately fatal than that of the ventricle; this difference depending probably on some obstruction to the free escape of blood being offered by an irregular contraction of

the muscular fibres, owing to their structural arrangement, in the wall of the ventricle. In exceptional cases, life may be prolonged for some days, or recovery has been known to occur, and even although a foreign body remain lodged in the heart. In one instance Ferrus relates that a man lived twenty days with a skewer transfixing the heart from side to side. In another case, a boy lived five weeks, with a piece of wood, three inches long, sticking into the right ventricle; as discovered after death by Messrs. Davis and Steward. A soldier, whose case Latour records, lived for six years after a wound in the right ventricle, from a musket ball which remained lodged against the septum; and Carnochan relates that a man lived eleven days with a bullet deeply buried in the apex of the heart.

*Rupture* of the heart, without penetrating wound of the chest, is generally fatal almost instantly; but life may be prolonged for some hours, fourteen hours elapsing after rupture of the right auricle, as recorded by Rust.

In two instances on record, the chest has been completely transfixed, and yet the individuals recovered and lived for years afterwards. One such case occurred in the person of a sailor, whose thorax, through the cardiac region to the back, was transfixed by an iron-pointed shaft which fell on him from a height on board ship, pinning him to the deck. The shaft was with some difficulty extracted through the chest. I had an opportunity of examining this man many years afterwards, and he was then in good health and without thoracic inconvenience. I communicated a report of the examination I made, to the *Lancet*, about 1859; the exact date I cannot find, while writing this reference. In another instance, transfixion of the chest by the shaft of a chaise was followed by recovery of eleven years' duration. The original history of both these remarkable cases with the instruments of penetration, are preserved in the Museum of the Royal College of Surgeons.

*Treatment.*—A penetrating wound of the chest presents certain general indications of treatment. (1) Hæmorrhage must be arrested. The wound may be accompanied with hæmorrhage from two sources; the arteries of the parietes, or the vessels of the lungs. The former are rarely the source of hæmorrhage. An *intercostal artery* is seldom wounded, the vessel lying under cover apparently of the groove in the lower border of the upper rib of the two. Yet occasionally the artery bleeds freely. The integumental wound must then be enlarged, if necessary, to reach the bleeding vessel, which may be secured by ligature or torsion. Compression may sometimes be more practicable; and this is best accomplished by introducing a piece of rag in the form of a bag, and stuffing it with small pieces of lint, so as to compress the vessel effectually on drawing the stuffed bag outwards. The internal mammary artery, which is rarely wounded, must be ligatured or twisted, the external wound being enlarged when necessary for this purpose. The costal cartilage overlaying the artery may be divided in order to reach the vessel. Blood extravasated into the anterior mediastinum or the pleura, can be partly withdrawn through a female catheter or by the application of a cupping-glass. *Pulmonary* hæmorrhage is the chief source of danger; but the treatment is constitutional, and will be specially noticed after completing the local management of the wound. (2) Foreign bodies are sometimes discovered on carefully examining the wound by gently introducing the finger. A probe should never be used, lest a simple integumental wound

be thus accidentally converted into a penetrating wound of the chest. Any foreign body within reach that can be fairly extracted, or by enlarging the wound, must be removed; such as clots of blood, a splintered bit of rib, or a bullet. If not accessible, the substance had better be left to find its way out; or, remaining within the chest, it may lead to the formation of abscess and be coughed up with purulent expectoration; or, the body may become encysted and quiescent, thus lodging in the chest for years. A bullet has been known to continue rolling loosely about in the pleural cavity. (3) The closure of a penetrating wound of the chest, should be determined by two considerations; the probability of a foreign body still remaining in the wound, and by whether the lung be wounded. A *small* puncture, without the escape of air and blood during expiration, and unaccompanied with bloody expectoration, is a condition which permits of the wound being closed. This can be done effectually by means of the ordinary appliances; one or two sutures perhaps, a pad of lint and strips of plaster. A rib-bandage may be applied to restrict the breathing to abdominal respiration.

A wound of the chest which involves the *lung*, air and blood escaping through the wound from the injured lung, is a condition wherein the external wound should not be closed. Water dressing may be applied, but the patient should be placed on the wounded side, in order that the air and blood may be freely discharged. Pneumothorax and the tendency to emphysema, and perhaps hæmothorax, will probably thus be prevented. This general rule, as to the position of the patient, must not be made absolute. If the position prove intolerable, he may be allowed to lie in whatever position is most comfortable to him; but the almost inevitable consequences of an unsuitable position should not be overlooked.

*Constitutional* treatment consists in the remedial measures appropriate for arresting pulmonary hæmorrhage. Perfect quietude, so that the breathing shall be as placid as possible, must always be enjoined; for healthy pulmonary texture evinces a strong natural disposition to heal. Astringents may then be administered with advantage, and in particular gallic acid, alum, or acetate of lead and opium. Opiates are also remedial by ensuring sleep, and diminishing the respiration. The efficacy of blood-letting in reducing the force of the circulation, as originally inculcated by John Bell, Hennen and Guthrie, was corroborated by the large experience gained during the Crimean War. Venesection should be had recourse to early and copiously, sixteen or twenty ounces of blood being drawn at once, and repeated to a lesser amount again and again, whenever necessary to suppress hæmoptysis. I am in favour of one decided, and as it may be termed, knock-down blood-letting, when the pulmonary lesion will probably undergo repair sufficiently to arrest hæmorrhage before the pulse rises and bleeding can recur.

*Inflammation* supervening after about the third day, it should be met by the usual antiphlogistic treatment; with this difference, that antimony and mercury are scarcely appropriate, owing, as Mr. Lawson has observed, to their influence in checking the exudation of plastic lymph requisite for the reparation of the wounded lung.

*Secondary* hæmorrhage may arise from inflammatory excitement of the circulation, or after gunshot wound, by the detachment of sloughs, either from the lung, or from an injured intercostal artery. Venesection is the remedy in the first case; and astringents in the latter two, with

ligature or compression in the third case. The pleural cavity may have become filled, and the lung compressed by air, extravasated blood, or inflammatory effusion, serous or purulent; the wound should then be opened with a probe-pointed bistoury and free vent given to any such collection.

**HERNIA OF THE LUNG OR PNEUMATOCELE.**—Protrusion of the lung may follow a penetrating wound of the chest; or, arising after the external wound has healed, it appears under the cicatrix; and it has been produced by fractured rib without wound, or by any violent straining effort, as during labour. Always a rare accident; the protrusion is only properly speaking hernial, when covered with integument, a very rare occurrence. Any part of the thoracic parietes is liable to hernia of the lung; but more especially one or other side of the chest. The tumour may attain a large size.

**Treatment.**—With an external wound, and the protruding lung in a healthy state, it may be returned into the thorax; and the treatment otherwise is that of a penetrating chest wound. Or, the protruding portion of lung may be allowed to remain as a plug to the pleura, according to Mr. Guthrie's recommendation, when it soon granulates and heals over. This should certainly be the rule if the lung be in a sloughy state. Such an exposed portion has been known to slough away. It has also been removed surgically and successfully, even although of considerable size. Tulpius ligatured a gangrenous protrusion of the lung, and cut it off with scissors. The piece removed weighed three ounces, yet the patient entirely recovered. Hernial protrusion must be supported by a truss.

**PNEUMOTHORAX.**—Distension of the pleural cavity with *air*, and an accompanying collapse of the lung, is denoted by certain marked signs; tympanitic resonance on percussion, with an absence of the respiratory murmur and an increased or puerile respiration on the opposite side of the chest, as discovered by auscultation. The breathing is of course embarrassed in proportion to the pleural distension and pulmonary collapse.

The *causes* of this condition are, surgically, any occasion of wound of the lung; whether by a fractured rib, rupture from thoracic compression, or a penetrating wound of the chest, as by a stab or bullet. But pneumothorax may also arise from a diseased state of the lung, as the bursting of a pulmonary abscess into the cavity of the pleura; air and fluid thus co-existing in this cavity, the fluid below and the air above. Two distinctive signs are then presented; a splashing sound elicited by succussion or shaking of the chest; and metallic tinkling, a clear, silvery, bell-like sound, resulting from the dropping of fluid occasionally from the pulmonary orifice into the fluid collected at the bottom of the pleural cavity. Coughing will frequently elicit this sound.

**Treatment.**—The relief of pneumothorax is easily accomplished by tapping or puncturing the chest so that the accumulated air shall escape from the pleura,—the operation of Paracentesis Thoracis. But the causes of which pneumothorax is itself only symptomatic must then be attended to, as in the treatment of a penetrating wound of the chest.

**Emphysema.**—Distension of the *cellular texture* with air frequently accompanies pneumothorax; although either condition may occur independently. Emphysema almost necessarily depends on a wound of the costal pleura, in conjunction with that of the pulmonary pleura; air escapes into the pleural cavity with each inspiration, and is expelled

thence into the cellular texture. If the lung be bound down by adhesion at the seat of both apertures, the air passes directly into the cellular texture; emphysema arises without any previous pneumothorax. An external penetrating wound will also allow air to pass directly into the cellular texture, thus giving rise to emphysema.

A rare mode of production, which Mr. Hilton has described, is by rupture of the pulmonary texture alone; air passing into the posterior mediastinal cellular texture, along the course of the nerves and vessels, thence to the neck, and downwards along the sheaths of the arteries to the limbs.

The *signs* of emphysema are distinctive; a swelling, diffused, somewhat elastic, but plainly crackling under pressure with the fingers, and without any discoloration of the integument. This swelling arising in the neighbourhood of a fractured rib, or around the margin of a penetrating wound, gradually extends through the cellular texture over the thorax. Sometimes it passes up into the neck and arms, and downwards to the lower limbs; such general emphysema presenting the singular appearance of a stuffed figure scarcely human; and as the internal organs become involved, dangerous symptoms ensue, particularly dyspnoea, threatening suffocation.

*Treatment* specially for this condition may not be requisite. The air infiltrated often undergoes absorption rapidly, and the swelling disappears. Bandaging may have some repressive and absorbent effect. Punctures well placed more decidedly control the spread of emphysema; and an external wound, when present, may sometimes be opened with advantage to aid in discharging the imprisoned air. Should respiration become oppressed, venesection freely employed, will often afford the most marked and instantaneous relief. I cited a case in point from my own observation, when treating of fracture of the ribs.

**HÆMOTHORAX.**—The presence of *blood* in the pleural cavity gives rise to different symptoms from those of Pneumothorax. Hæmorrhage may be suspected by dulness on percussion, with absence of the respiratory murmur, dyspnoea more or less urgent, and collapse; arising in connexion with a fractured rib, or a penetrating wound of the chest. The blood may proceed from the lung or an intercostal artery. Secondary hæmorrhage, and the circumstances under which it supervenes, may also produce hæmorthorax. Blood thus extravasated soon undergoes putrefactive changes, and leads to the formation of pus in the pleural cavity—*empyema*.

*Treatment.*—An early opening must be made, both to relieve the breathing and to prevent the risk of empyema. Advantage should be taken of an external wound to make that the vent; a probe-pointed bistoury being carefully used to free the opening. A cupping-glass may be applied to withdraw the blood, if it be not readily discharged. If the hæmorrhage be *persistent* and symptoms of hæmorthorax return, the plan recommended by Guthrie may become advisable. The wound is to be closed, so that the blood accumulating in the pleural cavity may compress the orifice in the lung, and thus arrest any further hæmorrhage; the patient lying on that side as an additional pressure on the wounded and bleeding organ. After the lapse of six or eight days, the wound should be reopened, or tapping may be performed, to evacuate the imprisoned blood; which, if allowed to remain longer would probably provoke empyema.

**HYDROTHORAX.**—A collection of *serous fluid*, or water, in the pleural

cavity, may be the result of pleurisy: but more commonly the condition arises from disease of the heart or lungs, obstructing the circulation. Both sides of the chest may be affected.

The signs are those of empyema, without the accompanying hectic fever.

Treatment surgically has regard only to the relief of dyspnoea by evacuation of the imprisoned fluid,—the operation of paracentesis thoracis.

**EMPYEMA.**—A collection of *pus* in the pleural cavity is usually the consequence of pleuritis; induced by a wound of the pleura from a fractured rib, or a penetrating wound of the chest. The lung, may, or may not, be implicated. Occasionally, the irritation of a carious rib, or the bursting of an abscess into the chest, is the cause of empyema.

The *signs* are, dulness on percussion and absence of the respiratory murmur at the lower part of the chest, up to the level of the fluid; this varying with the upright or recumbent position of the patient. *Ægophony*—a bleating or reedy voice sound, something like Punch's voice, is heard at the upper part of the chest; owing probably to a thin layer of fluid rising up between the two layers of pleura, through which the voice is transmitted, as a broken vibratory voice, from the larger bronchial tubes. Pus continuing to collect in the pleura, the line of percussion dulness gradually rises higher and higher; until the whole side of the chest emits a wooden sound on percussion, and neither breath nor voice sound can be heard. The affected half of the thorax is increased in size, visibly and palpably, and as shown by measurement, compared with the opposite side. The intercostal spaces are widened and bulge outwards between the ribs; while the lung is compressed backwards towards the spine, becoming consolidated like unto the consistence of india-rubber, and ultimately perhaps not larger in size than a fist. Empyema of the left pleural cavity displaces also the heart towards the right side; or if it occur on this side, the liver is depressed by the pleural accumulation. Dyspnoea is more or less urgent as the disease progresses, and the usual hectic fever results from continued suppuration. The abscess may point and burst externally, between the ribs.

*Treatment* surgically, consists in evacuation of the imprisoned fluid.

**PARACENTESIS THORACIS.**—Tapping the chest is an operation for the evacuation of any fluid—air, blood, serous-fluid, or pus, collected in the pleural cavity; but it is especially and more commonly performed for the relief of the latter accumulation,—empyema.

The spot selected for puncture is wherever the abscess may have pointed, or where there is decided dulness,—that the lung shall not be wounded; and the place usually chosen is in the fifth intercostal space, at about its middle on the side of the chest. This about corresponds to the insertion of the serratus magnus. A slight incision is made at this spot,

FIG. 395.

with the point of a bistoury; a large-sized, flat-shaped trocar (Fig. 395),

is then thrust slantingly over the *upper* margin of the sixth rib, thus avoiding the intercostal artery, and passed through the pleura. The trocar is withdrawn and the fluid drawn off through the canula. Air is liable to enter the thorax towards the end of the stream; it having become almost dribbling, air may then be sucked into the pleura during expiration, to fill up the thoracic space unoccupied by the collapsed lung. Decomposition of the purulent fluid would thus be induced, and severe or fatal constitutional disturbance. To obviate any such risk, the canula should be provided with a stop-cock, which is turned as the trocar is withdrawn; an india-rubber bag is then attached to the projecting end of the canula, and the fluid safely drawn off; the stop-cock being turned, and the bladder emptied and reapplied, as often as may be necessary to evacuate the purulent collection. A modification of this method is preferable. A long india-rubber tube, instead of the bag, having been fixed to the canula and its free end placed in a basin of water; the fluid is drawn off as safely under water, and with the advantage to the Surgeon of his being enabled to see when the stream ceases. On withdrawing the canula, a pad of lint is slid over the puncture-orifice in the integument, and secured by strips of plaster. A rib-bandage may be used to restrict thoracic respiration. The *drainage-tube* of M. Chassaignac, and adopted by Dr. Goodfellow and Mr. De Morgan, may be employed to prevent any reaccumulation of pus. A long iron probe, slightly bent, is introduced through the trocar-opening, and pressed against an intercostal space posteriorly, as low down as possible. The projecting end having been distinctly felt, it is cut down upon, and pushed out. A silk thread carrying the drainage-tube is attached to the eye of the probe, and on withdrawing the probe at the lower opening, the drainage-tube follows through the pleural cavity; the ends of the tube, projecting from the opposite openings, are tied together, and the purulent fluid drains away, *guttatim*, as it forms. I remember to have read a case in which Mr. Berkeley Hill adopted this resource, in an old-standing empyema, and with most marked advantage to the general health.

**HYDROPS PERICARDII.**—A collection of water in the pericardium may result from the same causes obstructing the circulation, as those of hydrothorax; the two conditions not unfrequently co-existing.

The *signs* are; percussion-dulness, extending over the whole pericardiac region, and absence or muffling of the cardiac impulse, with perhaps an obvious fulness to the eye, and to the hand placed over this region. There is constant præcordial oppression and dyspnoea, particularly in the recumbent posture, and faintness on exertion.

*Paracentesis Pericardii* may be employed as a last resource. A spot of the greatest dulness having been selected; a slight incision is made in the intercostal space, and a small trocar passed obliquely into the pericardium.

**DEFORMITY** of the Chest and Spine will inevitably result from pleurisy with extensive adhesion, or from tapping the chest, as for empyema, when the lung cannot sufficiently undergo expansion. In either case, the side of the chest collapses to meet the inactive lung, and there is more or less flattening deformity.

No mechanical contrivance will be able to control this result. The case is best left to nature, and if the patient be young, he may outgrow the deformity.

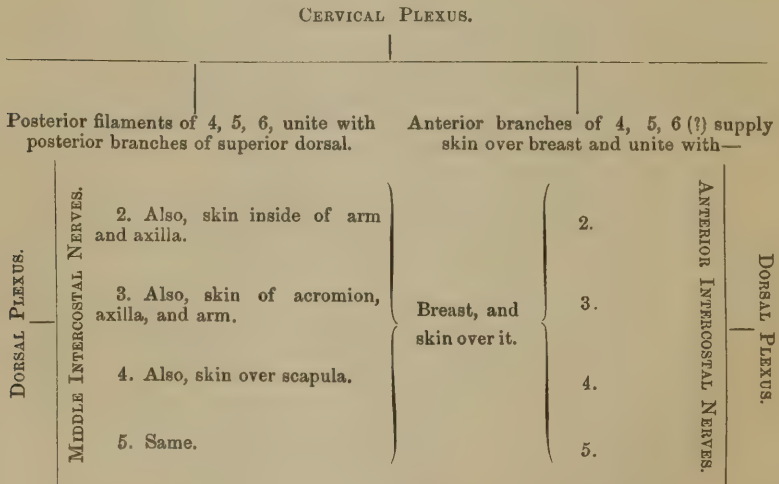

## CHAPTER L.

## DISEASES OF THE BREAST.

IN considering Diseases of the Breast, it is absolutely necessary to regard the Mammary Gland in its physiological and anatomical relations; through the nervous, vascular, and lymphatic systems.

The Breasts,—meaning thereby the Mammary Glands, are intimately related, physiologically, with the organs of reproduction, in the female. A healthy condition of these organs is associated with a healthy state of the breasts, and both undergo, concurrently, corresponding differences of functional activity at different periods of life;—before puberty, at puberty, and subsequently, periodically during the menstrual period, and during pregnancy, parturition, and lactation.

The anatomical relations of the breast have reference principally to its intimate nervous connexions; by the distribution of the spinal nerve-filaments to the skin over the gland, to the gland itself, and their connexions with the cutaneous filaments of the contiguous regions. This nervous system of the breast, and its source of supply from the general nervous system, is clearly exhibited in the following diagrammatic scheme of *innervation*, by Mr. Birkett.

It should be read thus. The breast and superimposed skin are supplied by filaments from the anterior branches of the 4th and 5th cervical nerves. Filaments from the posterior branches of the same nerves join with others from the superior dorsal nerves. Filaments from the middle and anterior intercostal branches of the anterior division of the 2nd, 3rd, 4th and 5th, nerves of the dorsal plexus, supply the breast

and skin over it chiefly. A minute examination demonstrates the association between the 2nd intercostal and filaments supplying the skin of the inside of the arm and axilla; also the same parts, and the skin about the shoulder from the 3rd; and the skin about the scapula from the 4th and 5th. These nervous intercommunications explain the widely-extended pain of which patients so grievously complain when affected with mammary hyperæsthesia.

*Arteries and veins.*—The 2nd, 3rd, 4th, and 5th, intercostal branches of the internal mammary artery usually supply blood to the sternal segment of the breast; within the axillary portion, a large branch from the axillary artery commonly ramifies; and the inferior and lateral regions receive a few branches from the intercostal arteries which accompany the nerves through the middle intercostal foramina. The *veins* accompany the arteries and terminate in the internal mammary and axillary trunks. The subcutaneous veins around the areola, are arranged in the form of a circle,—the *circulus venosus areolæ* of Haller. The superficial veins, ramifying over the breast, are often dilated, and present a blue, open network.

*Lymphatic vessels.*—The superficial lymphatics pass through the axillary, the cervical, and anterior mediastinal glands; a deeper series pass over and beneath the pectoralis major muscle to the glands under the clavicle.

GENERAL PATHOLOGY AND DIAGNOSIS OF DISEASES OF THE BREAST.—The mammary gland is liable to the same kind of diseases as other organs; but the physiological relations of this organ give it an almost specially wider range of pathological significance, it being the scene of sympathetic uterine affections, and of inflammation and morbid growths, as perversions of nutrition,—the liability to which varies according to the functional activity or quiescence of the gland.

The general *diagnosis* of diseases of the breast must have reference, therefore, to the following considerations, which may be conveniently embodied in the following inquiries, taken successively:—Has the disease, in question, any manifest connexion with the age of the patient; the stage of development of the gland; its functional activity or repose; and the social condition of the patient, as to marriage, &c.? Does it seem to be associated with any disturbance of the functions of the generative organs? Is it merely a local affection, or more intimately connected with general constitutional dyscrasia? Is it of inflammatory origin? Is it traceable to a morbid state of the excretory ducts, or of the secreting structure of the gland? And lastly, is the swelling, tumour, or tumefaction really produced by something growing in the breast,—a new growth, infiltrating the tissues of the breast, inflammatory or otherwise; or simply a morbid condition of a part or whole of the actual tissue of the organ,—an excited state of the gland-structure;—in short, is the disease superadded to the gland, or a morbid state of the gland-structure?

It will be observed that this sequence of inquiry is analytical, and that it proceeds in the order of exclusion; both of which aspects of inquiry are most valuable in clinical teaching and in personal investigation. But he who has been thus trained, will come at last to conduct such inquiry unconsciously, or to cut it short, by at once associating the leading characters of the disease, in his recognition or diagnosis of that disease.

*Method of examining the Breast.*—The following practical directions—according to Mr. Birkett—will be found to facilitate the diagnosis of a

morbid lobe of gland-tissue from a new growth. Press the indurated part gently between the thumb and fingers, and a tumour is so distinctly felt that the positive existence of something superadded to the breast is affirmed; but now place the fingers lightly and *flatly* upon the part over the site of the supposed new growth, pressing gently against the thorax, and nothing more than the ordinary gland-tissue is perceptible. On the contrary, if there be a genuine new growth, something developed recently within the normal gland, it will be always felt, in whatever manner or in whatever position the patient is examined. For perfect accuracy of diagnosis, the breast should be examined whilst the patient is seated, and also when placed in the recumbent posture.

**INFLAMMATION.—MASTITIS.**—The earliest change is induration more or less intense, and involving one or more lobes of the gland. Uneasiness, rather than pain, is experienced in moving the arm or in the act of suckling. The lump, knot, or coring of the milk, as it is termed, is due to congestion of the milk in the part affected. This congestion and induration increase with variable rapidity, and the whole gland becomes involved. Integumental swelling and redness supervene with acute pain, and considerable constitutional disturbance or inflammatory fever.

*Suppuration* takes place, and pus collects in the breast, behind it, or on its cutaneous surface. The formation of mammary abscess may, therefore, be either *super-mammary*, *intra-glandular*, or *sub-mammary*. These different situations of abscess can only be distinguished by careful palpation with the fingers, as to the depth of fluctuation. Sub-mammary abscess is the most characteristic. The breast seems to rest upon and be projected by something behind it, and which yields on slight pressure, the elastic fluctuation of an air-cushion. The matter progresses towards the integuments slowly; it points very often, at several spots around the circumference of the gland, or making its way between the lobular masses of the organ, an opening forms near the areola towards its sterno-clavicular border.

*Causes.*—Inflammation of the breast occurs commonly in the adult female, and during lactation; leading to the formation of *milk abscess*. During pregnancy and weaning, the inflammation happens very rarely; more commonly during the former than the latter period, and when at the time of weaning, it is usually excited by an abrupt discontinuance of suckling—owing to the death of the infant or illness of the mother. Some local irritation, not unfrequently, induces it; especially ulceration of the nipple, obstruction of a milk duct, contusion or exposure to cold; and occasionally a diseased state of the axillary glands. On the other hand, the inflammation very rarely arises before puberty, about that period, or during the inactive state of the gland.

*Treatment.*—The usual treatment of inflammation is here applicable, but it should be had recourse to at an early period; in order to anticipate as far as possible the known circumstances under which the disease usually arises, and prevent its suppurative consequences in the destruction of the breast.

In the first instance, repressive measures should be employed; cold lotions, or the extract of belladonna thickly spread on strips of lint and well applied over the whole breast, a most effectual repressor of incipient inflammation concurrent with lactation; occasionally, leeches may be advisable, and derivative aperients when circumstances permit. Additional, and special, relief is afforded by emptying the gland-tissue of its secre-

tion; removing, in fact, lactic congestion. Suckling need not be abandoned, but it may be necessary to remove the milk mechanically, by means of the breast-pump. The arm of the affected side should be placed at rest, and the weight of the breast supported on the patient's chest; or if she lie sideways, a pillow or loop of broad bandage may be requisite. Established inflammation with redness of the skin, and almost inevitable abscess, must be met by warmth and moisture; poultices, to limit the inflammation and induce suppuration of a circumscribed character, and facilitate pointing of the abscess. The usual rule of an early, free, and dependent opening is here imperative. The support of a bandage will then be requisite to prevent any tendency to bagging of matter; and subsequently, to promote absorption of the remaining induration, when the pressure of cross-strapping with long strips of adhesive or soap plaster will probably afford a more even and suspensory support to the breast.

*Chronic inflammation* may be the consequence of acute inflammation, or arise independently as a scrofulous affection. Induration and swelling of the breast, in part or of the entire breast; is usually followed by suppuration, burrowing, and sinuses or fistulæ of an obstinate character.

Chronic abscess must be distinguished from cystic tumour of the breast. Both having a painless and an indolent character; the history will partly distinguish abscess, and puncture with a grooved needle will always determine the diagnosis.

The *treatment* consists in the evacuation of matter, as occasion requires, and the support of strapping or bandaging; with a tonic and nourishing course of general treatment. Chronic sinuses may be closed by stimulating injections, or by laying them open as a last resource. Milk fistulæ will not usually heal until the secretion of the gland is arrested.

*Scrofulous enlargement*, or tumour, of the Breast, is a result of mammary inflammation in scrofulous subjects. This affection is occasionally met with. Tuberculous deposit also is noticed by Velpeau, and as occurring in two situations; in the gland, or in the skin and subcutaneous cellular textures. The *axillary glands* are sometimes the seat of this deposit. Thus, I removed a conglomerate bunch of these glands from the axilla of a middle-aged, single woman; the deposit being yellow, opaque tubercle, mixed with cretaceous matter.

*Inflammation of the Nipple*.—This affection often arises during suckling, and leads to superficial ulceration or excoriation as *cracks*, *fissures*, or *chaps*. Great pain attends the act of suckling, and inflammation of the breast may be induced.

*Treatment*.—Frequent ablution with warm water often proves more remedial than lotions, ointments, or other applications. These may be simply protective; as collodion, glycerine, almond oil, or some dry powder, as prepared chalk or flour dusted around the nipple; stimulating applications, as a touch with nitrate of silver; astringents, as tannin or zinc ointment; and narcotics, to relieve pain. The difficulty is to manage the breast in a state of secreting activity, and the suckling of the child, the nipple or perhaps both nipples being sore. Some of the above mentioned applications would be decidedly poisonous to the infant; narcotics in particular. Various shields have been devised to protect the nipple from the pressure and dragging caused by the act of sucking; and such a contrivance will also shield the infant's mouth from any noxious matter left around the nipple, by the use of these curative applications.

*Abscess of the Nipple* or of the areola, has no special characters or treatment.

Other diseases of this part, as tumours, are not peculiar.

CHRONIC INDURATION of portions, or of the whole of the mammary gland is another common condition; the induration having a finely *lobular* or *granular* character, owing to the acini or cæcal terminations of the lactiferous ducts being gorged with epithelium. This state of the gland may be found in breasts of all sizes and shapes; in the large, heavy, pendulous breast; and in the small, atrophied, disc-shaped organ. The one feels like a great ball under the integuments; the other, under which the tips of the fingers may be inserted, feels like a quoit covered with skin. Indurated portions simulate tumours formed by a new growth; but, although distinctly felt when pressed between the finger and thumb, when pressed flatly against the chest, any such portion is imperceptible as a hard mass. Great tenderness, and even pain amounting to agony, on the slightest handling, is often experienced; the patient's face becoming suddenly suffused with a bright red blush, or pallid, while a sensation of nausea or faintness oppresses her. The pain has two other characters besides its intensity; it is widely distributed, shooting up the neck, or behind to the back and particularly to the scapula, and often down the arm; and this pain may be traced to the middle or anterior branches of the intercostal nerves, which are painful on the slightest pressure, the filaments of the painful nerve or nerves being distributed to the indurated portion of the breast; the pain is also paroxysmal, and it may pass from one breast to the other as an alternate affection. No trace of any inflammation of the integuments can ever be discovered. The general health is much disturbed, and the nervous system highly excited.

The *cause* of chronic mammary induration seems to have reference to functional derangements of the generative organs, and which may be of an opposite character; amenorrhœa, menorrhagia, dysmenorrhœa, or commonly profuse leucorrhœa. Unmarried women, between twenty-five and forty years of age, are most subject to these indurations; and of the married, sterile women are far more frequently affected.

*Treatment* is chiefly constitutional; tonics, such as iron, quinine, the mineral acids, and occasionally sedatives, have the most beneficial influence, coupled with the hygienic regimen of hysteria. Menstruation may sometimes be rectified by remedies which directly influence that function. Of topical applications, evaporating lotions and sedatives are most appropriate; and when the breast will bear pressure, simple strapping, or with emplastrum ammoniaci cum hydrargyro, may aid in dispersing the induration.

IRRITABLE MAMMA.—A condition of hyperæsthesia or exalted sensibility of the skin covering the breast, as well as of the gland itself, is not an uncommon affection. The breast is somewhat enlarged, firm and conical, the nipple swollen, and the skin generally reddened. But the *pain* is the most prominent symptom, it being induced by the slightest touch, and even by the gentlest contact of the dress. It is very widely distributed, and paroxysmal, alternating possibly from one breast to the other.

Young girls are more subject to this affection than women above the age of twenty-five; and it seems to be of uterine origin, but is probably induced by depraved habits.

The *treatment* is similar to that of chronic induration of the mamma.

HYPERTROPHY.—Simply an overgrowth of the gland itself, is a very

rare modification of the nutrition of this organ. The size attained may be enormous; the two overgrown breasts being a perfect burden and misery to the individual.

Hypertrophy of the breast occurs in two forms, presenting a very different appearance; the large, firm, globular breast, with tense over-spread integument; and the large, flaccid, pendulous breast, with shrivelled, wrinkled integument, the component masses of the gland having a loose connexion, and the nipple small, although the areola is of larger area than usual. Occasionally, the latter form of hypertrophy, is associated with a new growth—an adenocoele.

The *cause* of this mammary hypertrophy seems referable to uterine derangement. It commences soon after puberty or in early adult life; in single as well as in married women, and menstruation is generally more or less deranged. But overgrowth, thus apparently excited, by the commencement of uterine life, is quite distinct from a merely functional enlargement of the organ associated with amenorrhœa.

No *treatment* has much control over this condition, either in arresting its progress or promoting its reduction. The preparations of iodine may be tried, and the special medicinal agents with hygienic measures which influence the catamenial function. Amputation has been resorted to in extreme cases, and after the removal of one breast the other has much diminished.

*Hypertrophy* of the *Fat* around the Mammary gland, is occasionally seen; the breast thus attaining possibly to an enormous size. In one such case, which my colleague Dr. Cockle showed me, the fatty breasts of a young woman, aged nineteen, weighed each about eleven pounds. But, the tumour of the fatty breast is evidently *continuous* with the fat *around*; and this is its main diagnostic point of distinction from hypertrophy of the breast itself.

*Treatment* here also is of little avail. Liquor potassæ in large doses, as originally recommended by Sir B. Brodie for fatty tumour, may have some beneficial influence.

ATROPHY, or wasting of the gland-tissue of the breast, commonly takes place as the procreative function ceases in advancing life. The lactiferous ducts remain, and sometimes contain a tenacious mucus. The gland, otherwise, is very generally replaced by fat; thus presenting the outward form of the organ. In extreme atrophy of the breast, as found in old women, the arteries are not uncommonly converted into bony tubes; a degeneration of these vessels, of which specimens may be seen in the Museum of the Royal College of Surgeons, 2811, 2812; and one in Guy's Museum.

Occasionally, in early life, atrophy occurs; the gland not enlarging during pregnancy nor secreting any milk after parturition. Prolonged lactation and its rapid repetition, have an atrophying effect; and sometimes, weaning is followed by shrinking of the gland-tissue, so that scarcely any breast remains; the gland, however, resumes its size and secretory power, even more perfectly than in full-breasted women, during a subsequent pregnancy.

A new growth, as an adenocoele, forming in the breast, is often accompanied with wasting of the organ; and which may thus be almost replaced by the growth.

TUMOURS.—(1) ADENOCELE OR ADENOID TUMOUR.—The Chronic mammary tumour of Sir A. Cooper, Sero-cystic sarcoma of Sir B. Brodie,

and Mammary glandular tumour of Paget. This most common form of breast tumour is encapsuled and finely lobulated; its section has a bluish or greenish-white colour, which assumes a rosy tint on exposure to the air, and pressure of the cut surface exhibits drops of thick creamy fluid, consisting chiefly of epithelium. The tissue of this tumour closely resembles that of the gland itself; of which organ it might therefore be termed a *partial* hypertrophy or overgrowth, but as an encapsuled or *discontinuous* formation, it must be regarded as a new growth.

Two *varieties* of structure—according to Mr. Birkett—may be recognised; *fibrous* adenocoele, consisting of densely compact lactiferous ducts, perhaps containing a milky secretion; and *cystic* adenocoele, the cysts proliferous of glandular tissue from their interior, and containing a yellowish, transparent, serous fluid, afterwards dark and opaque. The cysts may be either a new formation; or result from the dilatation of lactiferous ducts, as Sir B. Brodie originally described their origin in sero-cystic disease of the breast. These two modifications of cystic adenocoele, differ in their origin, rather than structurally.

*Symptoms.*—Adenocoele usually commences as a small, hard, granular, circumscribed, and painless or scarcely tender, nodule or lump; situated upon the cutaneous surface of the breast, or at its border, in its substance, or behind it. When superficial, this lump is isolated and moveable under the skin; but when imbedded or behind the gland, these characters are indistinct or wanting. With an increasing size of the growth, the gland itself becomes atrophied. More than one such lump or many, may possibly be developed, varying in size from half an inch to two or three inches. Both breasts seem equally liable to this affection, and both may be affected, though rarely.

*Cystic* adenocoele is distinguished by fluctuation, more or less perceptible, according to the superficial or deep situation of the growth; this character gradually disappears, as the cyst or cysts become solid, in part or entirely, owing to proliferous growths occupying their cavities more or less completely. The skin stretching over the tumour, usually accommodates itself to increasing distension, without ulceration ensuing; sometimes, however, the skin becomes involved, and a fungoid growth protrudes externally, or a peculiar ulcer is presented, the edges of which are thin and lie flat upon the intra-capsular growth, being neither inverted nor everted, nor adherent thereto.

*Causes.*—No age is exempt from adenocoele; it may commence about puberty, or subsequently, and most frequently at the stage of passive maturity of the breast, between twenty and thirty years of age. Single women seem most liable, and of married women, it occurs more often in those who have borne children; but rarely, during pregnancy. External injury, as a blow, is now and then, apparently, the exciting cause of adenocoele.

*Course and Terminations.*—Adenocoele grows with a varying rate of progress; the originally solid and fibrous form enlarges slowly; the cystic form increases more rapidly; and either variety may attain a large or even enormous size, and a weight of many pounds. The general health remains unaffected, excepting when a fungoid growth reduces it by continued discharge. Sometimes, the tumour remains stationary, and occasionally it disappears. After removal, it seldom reappears; the fibrous variety very rarely, the cystic variety less unfrequently; and youth confers a decided immunity to recurrence, no return having ever been

met with, by Mr. Birkett, when the tumour had originated before thirty years of age. Recurring adenocoele may alternate from fibrous to cystic, and a third tumour return in the fibrous form of growth.

The *diagnosis* of adenoid tumour from other tumours of the breast, must be determined by reference to the *whole* of its pathology; in respect to the characters of the tumour, its causes, course and terminations. The points of distinction between adenoid and cancer of the breast, are most important. They are mainly, the absence generally of any implication of surrounding parts by infiltration; as of the skin, with retraction of the nipple, and ulceration of the integument over the tumour, and never any enlargement of the axillary or other neighbouring lymphatic glands; the general health also remaining unaffected. *Cystic* adenocoele more apparently resembles cystic cancer, and particularly when the growth has advanced to the condition it occasionally assumes, that of a protruding fungoid mass. But here again, the absence of any contamination of the neighbouring lymphatics, and of constitutional cachexia, are the turning points of distinction.

*Treatment.*—*Excision* of the tumour is the only certain cure. An incision is made over the lump, laying open its capsule, and the growth is then easily enucleated with the handle of the scalpel; thus sparing the mammary gland, and possibly without cutting it. The removal of a large tumour may necessitate excision of the gland as well. *Absorption* of an adenoid tumour is a rare event in nature, and but little under the influence of any known local applications or general treatment. The preparations of iodine, in the form of ointment and taken internally, have been recommended, as having some effect; and compression by means of Arnott's slack-air cushion, is said to have proved especially serviceable, in promoting absorption.

(2) **FIBROUS TUMOUR** of the breast is described by some authors, and also its *recurring fibroid* variety. Both these growths are rare. Probably, some such tumours have been fibrous adenocoele. Their pathology and treatment by excision, require no special notice.

*Neuroma* is occasionally developed on the cutaneous nerve-filaments, or on those within the substance of the breast. It, also, presents nothing peculiar in connexion with this particular organ, whether as to its pathology or removal by operation.

(3) **FATTY TUMOUR**, as a new growth, has been found on the breast, within the gland, or behind it; a condition distinct from fatty hypertrophy of the breast, which is simply an overgrowth of the fat surrounding the gland. The diagnosis will always be difficult, but removal of the mass is the only cure.

Remarkable cases are recorded; Sir A. Cooper removed a tumour of more than fourteen pounds weight, Sir B. Brodie relates another case in his Lectures on Pathology and Surgery, Warren excised a tumour of eight pounds, and Mr. Roper of Croydon, sent to the Museum of Guy's Hospital (prep. 2300<sup>50</sup>), a fatty tumour, measuring twenty-three inches around its largest circumference, which had been growing in the side of the mammary gland for fifty-eight years; it was first noticed by the woman in her thirtieth year, and she died with it at the age of eighty-seven years. In the centre of the mass there was an irregularly-shaped piece of bone.

(4) **CARTILAGINOUS, and OSTEOID TUMOURS** are extremely uncommon. Their firm, lobulated character, is similar to that of such tumours in other parts; and the treatment is excision.

Sir A. Cooper relates an instance of tumour, partly resembling the cartilage of a young subject, and partly ossific, which had been growing in the breast of a woman for fourteen years; her age being thirty-two. Professor J. Müller also notices an instance of cartilaginous tumour in the mammary gland; while he adds three other cases of this species of growth, in one the parotid gland was the seat, and in two, the testicle.

(5) **CRSTS, and CYSTIC-TUMOURS.**—Cysts—single or unilocular, and multiple or compound, and having various fluid or solid contents, as proliferous cysts—are severally liable to form in the mammary gland; or they may be associated with, and embedded in, other species of new growth, constituting cystic tumours, and of different kinds, as cystic adenocoele and cystic cancers.

The origin of these cysts, and their contents, are the principal grounds of pathological distinction.

(a) *Sero-cysts.*—Single or multiple, thin-walled, and containing a clear, colourless or pale yellow tinted fluid, of serous character and never tenacious. No coagulation is caused either by heat or nitric acid. These cysts originate either as new formations, or possibly from dilatation of lactiferous ducts, with which they may communicate or appear as perfectly closed and independent cysts.

(b) *Duct-cysts,*—perfectly closed or communicating with a duct, and containing mucoid secretion; hence named also, *mucous* cysts of the breast.

(c) *Galactocoele* or *milk-cysts,*—produced by dilatation of a lactiferous duct or its sinus from obstruction, or by rupture of the duct, and escape of the milk into the surrounding connective tissue. A cyst-formation incident to suckling, and occurring, therefore, only during the period of lactation; it is rather a rare affection. The little tumour—presenting sometimes as an oblong fluctuating tube, near the nipple, may enlarge perceptibly every time the infant sucks, and thus increase rapidly; or it may remain almost stationary. The serum of the milk accumulated, undergoes absorption, while the more solid fatty matter and earthy salts are deposited; causing the swelling to decrease and become firmer or quite hard, unlike a cyst wall, or the deposit may take the form of a lacteal calculus.

(d) *Hydatid cysts*—are occasionally met with in the breast. Mr. Birkett verified two such cases; one in the practice of Mr. B. Cooper, and the other in that of Mr. Cooper Forster.

**SYMPTOMS.**—Certain characters are common to all cysts, and cystic tumours in the breast. A *single* cyst presents a globular tumour, having an elastic tension or fluctuation; more or less perceptible according to the superficial or deep situation of the cyst, and the thickness of its walls. *Multiple* or compound cysts present an irregularly lobulated tumour, otherwise having the consistence of a single cyst. *Cystic-tumour* resembles either of these conditions; in proportion to the cystic nature of the tumour; but associated also with a solid mass, bedding or enclosing the cyst or cysts.

Cysts are not essentially painful; they may become tender, owing to inflammatory action, or in nervous subjects. The skin is unaffected, excepting in the fungating tumour of proliferous cysts; and then, the neighbouring lymphatic glands remain uncontaminated, and the general health is unimpaired by any cachectic blood-condition. By these two particulars at least, cysts and cystic tumours, in common with all other

non-malignant growths, are distinguished from Cancer. In all doubtful cases, and many will be dubious, the diagnosis should be determined by an exploring puncture and examination of the exuded cyst-contents, before resorting to any curative operation.

**TREATMENT.**—*Absorption* of the contents of a cyst can sometimes be effected by the mere application of stimulating embrocations. Thus, Sir B. Brodie recommends, as having proved successful, a lotion consisting of equal parts of camphorated spirit and weak spirit, with about one-third of *Liquor plumbi*. This must be applied on a piece of flannel, once folded, over the tumour, and renewed six or eight times in the day and night until the skin becomes inflamed; then desisting for two or three days, and again using it. Three or four weeks or some months elapse before a cure is thus effected. On the same principle, iodine paint or blistering may be curative. *Puncturing* the cyst, followed by pressure, may obliterate the cavity by adhesive inflammation; or the introduction of a tent of lint will induce suppuration, and granulation from the bottom. *Excision*, by carefully dissecting out the cyst, is not unfrequently the best or only method of treatment; or it may be necessary to remove the gland, partially or wholly. Partial excision of the gland is apt to favour a recurrence of the cystic growth, in the remaining portion of the organ; but its entire removal is, occasionally, succeeded by cystic disease, or perhaps a cancerous affection of the cicatrix.

(6) **CANCER.**—The breast is peculiarly liable to be the seat of primary cancer: scirrhus, very commonly; encephaloid occasionally; colloid, rarely.

The disease appears, either in the form of an infiltrating growth, or as a circumscribed or tuberos growth; or, it may be cystiform, associated with a cyst or cysts.

*Scirrhus.*—The descriptions usually given in surgical works of the pathology and diagnostic characters of Scirrhus Cancer, are mainly taken from scirrhus of the breast, it being the most typical illustration of this species of Cancer. As such, the general pathology of Cancer may be advantageously referred to, in Part I.; while the more specially important features only of the disease, as affecting the breast, will here be noticed.

It may appear in the form of an intra-mammary tumour, or as infiltrating the whole organ, or upon its surface or circumference; or as affecting the nipple, or the skin. Commencing, commonly, as a *circumscribed* tumour, or lump, of small size, about that of a Spanish nut, hard and moveable: it occasions little or no pain and may remain unnoticed. Increasing in size slowly, this nodule acquires a granular or finely lobulated character, and is more fixed. Scirrhus *infiltration* of the gland commences as a diffused mass, and often of a somewhat square shape; hard and irregular, and soon contracting adhesions, it becomes fixed. Atrophy of the glandular structure sometimes accompanies the development of the cancer.

*Cysts* are liable to form in connexion with the scirrhus growth, constituting a cystic cancerous tumour; which is thus more irregularly lobulated, and partly solid, partly fluctuating more or less perceptibly, under pressure with the fingers.

The surrounding parts become involved, and the tumour is the seat of severe pain, variously described by patients, as shooting, stabbing.

burning, &c. The gland acquires adhesion to the pectoral muscle, and to the skin over the tumour, the integument being bound down and presenting a dimpling or puckering, or having a brawny character, and a glazed or greasy appearance with the pores enlarged; the nipple is often drawn in by the adherent and contracting gland,—presenting the appearance of retracted nipple. But this condition is not peculiar to cancer. Reddish brown discoloration of the integument, at some tightly adherent part, is followed by the formation of a crack or fissure, which scabs over, while ulceration proceeds underneath the scab. A scirrhus ulcer is at length formed, having the ordinary characteristic appearances; hard, thickened, and everted edges, around an irregular chasm, the surface of which has a grayish-green colour, and discharges foul purulent matter. This ulcer may remain nearly stationary for months or years; or increase rapidly by sloughing; or throw up large fungous granulations and undergo an imperfect cicatrization. But, the progress of the disease, thus hesitating and interrupted, goes on. The axillary lymphatic glands sooner or later become enlarged and indurated, or assume the form of an agglomerated bunch, itself also adherent, and which undergoes the further course of breast-cancer. In an advanced and extreme condition, the mammary gland and axillary glands become almost one continuous matted and adherent mass, extending through the cellular texture, connecting lymphatics, and skin of the breast and axilla; forming a sort of cuirass,—the cancer *en cuirass*, of French authors, and which is accompanied with much œdema of the arm. The supra-clavicular and cervical glands may also be implicated.

During the course of the disease, constitutional cachexia sets in, usually when the cancer begins to acquire adhesions, particularly to the skin; and both the local and constitutional infection may then proceed almost *pari passu*.

The deeper parts, and remote organs, may ultimately become the seat of *secondary* cancer. The ribs and intercostal muscles are affected more by the direct infiltration of cancer, giving rise to pleurisy, dyspnœa, and hydrothorax; but cancer may appear in the bones and result in fracture, or in the liver or uterus, and possibly escape detection during life. Exhaustion, consequent on prolonged discharge and the constitutional infection, is perhaps, the most frequent cause of death.

Scirrhus commencing in the *skin* of the breast, appears in the nipple, or as a tubercle, situated usually towards the axillary border of the breast. Spreading inwards to the gland, the course of the disease is the same, but it probably will have a more restricted range.

*Encephaloid* begins either in the substance of the gland, or occasionally, in the immediate neighbourhood. It appears as a circumscribed, globular tumour, of soft consistence, rather largely lobulated, and rapidly increasing in size. The skin is distended before the enlarging growth, and does not so readily become adherent, but presents a largely open network of veins. By its physical characters, the tumour might be mistaken for compound cysts; in that case, however, the skin retains a passive appearance. Sometimes the integument soon becomes inflamed and œdematous, and then the tumour simulates the characters of an abscess. But the breast rapidly undergoes a remarkable change of form, becoming conical and prominent; and the integument over the most projecting part assuming a purple hue, sloughs and forms a circular ulcer, through which the encephaloid growth protrudes as a fungoid mass, of a

grayish or bloody colour, accompanied with a foul, purulent and bloody discharge. Portions of this mass disintegrating and separating, further protrusion from within takes place, and still maintains the fungous mass; but rarely, the whole tumour thus sloughs out, and cicatrization ensues. The lymphatic glands are involved, although less readily than in scirrhus of the breast; and the constitutional cachexy is less marked, or absent.

*Colloid*.—This rare form of cancer of the breast, consisting of gelatinous substance, loculated by a delicate fibrous matrix, presents a tumour of a somewhat tense and elastic character,—not very distinctive. Mr. Erichsen removed one such tumour from the breast; it was non-adherent, and had attained the weight of six pounds, after growing for five years. Mr. Birkett has seen two examples, in both of which the nature of the tumour could not be identified, when in the breast. Isolated centres of the growth are disseminated freely around the principal mass, an important pathological condition with reference to the operation of excision for complete removal of the tumour.

This species of cancer is usually associated with scirrhus or encephaloid.

The *causative* relation of age and uterine activity to cancer of the breast, is diagnostically important. From the fortieth to the fiftieth year, or the fifth decade of life, is the age most liable to this disease, as affecting the breast. Of 158 cases collected by Paget and 62 by Lebert, the disease appeared in 22 only before thirty years of age. Before twenty years of age, Mr. Birkett has never seen a case. But Mr. Lyford and Mr. B. Cooper, each record one instance; the one at eight years, the other at thirteen years of age; and in the Museum of St. Bartholomew's Hospital there is a specimen removed from a girl aged sixteen years.

The following interesting Table gives the results of Mr. Birkett's experience in 458 cases, between the ages of 20 and 100 years, in decennial periods:—

Age from 20 to 30 years	19 cases.
" 30 " 40	100 "
" 40 " 50	193 "
" 50 " 60	97 "
" 60 " 70	34 "
" 70 " 80	6 "
" 80 " 90	7 "
" 90 " 100	2 "
	<hr/> 458 "

Unmarried women are said to be more prone to cancer of the breast than the married, and sterile women rather than those who are prolific. The fallacy of these notions is shown by Mr. Birkett by an analysis of 100 cases; 86 were married, and 14 only, single. Of the 86 married women, 73 were prolific, 4 had aborted, and 9 only were sterile. In relation to lactation, there does not seem to be any marked connexion between the imperfect performance of this function and the subsequent development of cancer; but it is a notable fact, that the disease is very rarely developed during pregnancy or suckling.

The origin of the disease is popularly attributed to some external injury, as a blow, or the pressure of a stay-bone; there is abundant

evidence to justify this belief, and that any injury to the breast, however slight in itself, may be the exciting cause of cancer-production.

*Prognosis.*—The average duration of life is about three years, or less than four; and scirrhus is less rapid in its course than encephaloid; the rare form, colloid, growing slowly. Scirrhus also proceeds more slowly in old people; there are many instances where the disease has existed for ten or twelve years, and in one instance, as related by Sir B. Brodie, for twenty-five years. Encephaloid proceeds most rapidly in young, and constitutionally healthy women. Generally, it may be stated; that the younger and more healthy the patient, and rapid the course of the disease, the prognosis is proportionately unfavourable.

*Treatment.*—The hygienic and medicinal treatment of cancer of the breast, and its removal by operation,—whether by excision or some other method, are two principles of treatment; each of which has its advocates, and to the exclusion of the other and opposite principle. Some Surgeons would treat all cases medicinally, and according to the natural course of the disease; others would, in all cases, extirpate the disease by operation. It is unnecessary to point to illustrations of these opposite views in the practice of Surgeons, present or past.

The truth, as in many other matters, lies between these two extreme rules of treatment. The intermediate plan has reference to the individual case, both with regard to the local condition of the cancer and the constitutional power of the patient.

Assuming a case to be thus ineligible for operation, the following plan of treatment should be pursued. The disease being a perversion of nutrition as manifested by a reproductive growth, the *pathological* and rational indication of treatment remedially, would be; to rectify this deviation of the nutritive process so as to arrest the growth of cancer, and possibly lead to a predominance of the reverse process,—absorption, and thence the eventual disappearance of the tumour. Any such control over the formative or vital changes in nutrition, or over the chemical changes of the nutritive material—any such mode of arresting cancer growth, is quite beyond our present knowledge of physiology and pathology, in respect to this process. It only remains, therefore, for the practitioner to avail himself of such knowledge as *experience* has supplied. A generally nutritious diet, as the phrase goes, will suggest the object to be attained, in the selection of dietetic resources; but it is absolutely necessary to watch and discover, in each case, what particular articles of diet are most suitable for the improvement of the patient's general nutrition, and may have any marked influence on the progress of the disease. Anodynes, applied topically and administered internally, not only relieve the often severe and prolonged suffering incident to this disease; but these medicinal agents are important adjuncts to our dietetic resources, in procuring sleep and repose of the nervous system, requisite for a more healthy nutrition. Thus, narcotics, and in particular the preparations of opium are highly advantageous; while conium-ointment is I think, the most soothing topical anodyne, although aconitine ointment or belladonna plaster may be equally so in some cases. The preparations of ether,—sulphuric and chloric, and chlorodyne, are most efficacious for the relief of paroxysmal pains of a neuralgic character; and here quinine and iron are serviceable, as tonics. But tonics have probably a yet deeper remedial value. Iron may have some restorative influence in proportion to the cachexia, which plainly denotes a morbid-blood condition, one element of

which is a diminution of the red-corpuscles. Quinine is remedial in sustaining the general circulation, and thus supplying the pabulum of an improved assimilation; while stomachic tonics, such as gentian, calumba, and humulus lupulus, aid the digestion or primary assimilation of food.

Thus then, there is apparently a running connexion between these known measures,—a nourishing, well-selected diet, anodynes, and tonics, and they constitute the principal resources of the hygienic and medicinal plan of treatment, in respect to Cancer. By combined observation and judgment in the application of this plan, and by pursuing it perseveringly, doubtless many cases of scirrhus of the breast have been kept in abeyance—and life prolonged far beyond the average period of duration in this form of Cancer-growth.

*Compression* has been extolled as having an almost or absolutely a curative efficacy. Various means have been employed; the slack air-cushion of Dr. Arnott, or plasters, which besides supporting the tumour may have some medicinal influence in arresting its growth. But the pretensions of this method are, I believe, now renounced, and indeed any such applications are generally discarded. The arrest of a reproductive growth, as cancer, is not to be accomplished simply by mechanical repression of the tumour,—nor in the face of its inherent power of growth, can the tumour be made to undergo absorption. Any apparently successful results of this principle of treatment have been altogether exceptional; and probably, therefore, were due to other concurrent causes of cure.

*Ulcerated cancer* must be treated as any other open sore, according to its varying condition. Sloughing should be met by poultices, and cleansing lotions of chloride of zinc, permanganate of potash, or carbolic acid; in conjunction with sedatives, such as morphia, conium or belladonna to allay pain. Hæmorrhage may be restrained by the ice-bag temporarily applied, or by means of astringent powders or lotions, such as tannin or tincture of the perchloride of iron. *Edema* of the arm, in the advanced stage of the disease, can be somewhat relieved by moderate bandaging and elevation of the limb.

*Conditions favourable for operation.*—In proportion to the purely local and isolated condition of the cancer; its removal is justifiable, or favourable—in relation to the prolongation of life. This local state carries with it a proportionate share of constitutional power. Hence, in the early stage of cancer, when it is as yet small, and moveable; without adhesions, or implications of surrounding parts,—either in the integument by adhesion or ulceration, or the lymphatic glands by enlargement and induration; and consequently when there is little or no constitutional cachexia; the breast may be removed with the *most* favourable prospect of prolonging life. Mr. Birkett extends this principle to some degree of advancement in the progress of the disease; as even then offering an advantage, compared with allowing it to run its course. That, therefore, an operation may be undertaken with advantage when the disease has extended to the skin without infiltrating the cutaneous tissue to a wide extent, when ulceration has taken place, and even when the axillary lymphatic glands are distinctly indurated and somewhat enlarged.

*The probability of cancer recurring in situ*, after removal of the original growth, by operation.—The statistics respecting this question are unreliable, whether as to the proportion of recurrent cases, or as to the average period of immunity, before the return takes place. But, experience shows that in a large proportion of cases, the disease returns;

generally also, in two or three years, as Sir A. Cooper and Sir B. Brodie both observed, and with a fatal termination.

*The probability of prolonging life, by operation*—The statistics collected by Paget and Sibley, respectively, are here to the point. Paget states, that of 139 cases, 75 were not submitted to operation, and of these the average duration of life was 48 months. Of 64 operated on, the corresponding average was a little beyond 52 months. But the *period of the disease*, when submitted to operation, makes a very important difference in its result. Thus, in the first two years of the disease, the proportion of deaths was much less in those operated on than in those who were left to nature and other treatment; being in the former less than 11 per cent.; in the latter more than 30 per cent. The longest duration of life in cases not operated on, was 18 years; in those operated on, a little beyond 12 years. Sibley finds that the average duration of life in unoperated cases was about 32 months; whilst in those submitted to excision of the breast, it reached 54 months. The *temporary relief* from suffering should, however, always be taken into account in considering the advisability of operation.

The *comparative advantages of excision*, and removal by *caustic* applications, may be thus summarily stated. The one method is expeditious, attended with little suffering, and certain of removing the whole of the diseased organ; if the operation be performed sufficiently free of the disease. The treatment by caustics is tedious, attended generally with excruciating pain, and very uncertain in its operation. In comparing the results of the two methods upon the constitutional progress or local recurrence of the disease, there is not a balance of evidence in favour of either. Both are commonly followed by a return of cancer *in situ*, or its development in distant parts. The mortality after amputation of the breast, as referable to the *operation* itself, is extremely small, not exceeding 6 per cent. or much less.

*Recurrent cancer of the breast*.—Cancer may return in the cicatrix, and subsequently implicate the glands; or in the glands without any previous affection of the cicatrix. *Cicatricial* scirrhus presents itself in the form of scattered tubercles or buttons of cancer-growth; a very characteristic appearance. The period of recurrence is uncertain; sometimes before cicatrization is completed, and having the character of a cancerous ulcer; or not until after some weeks or months of completed cicatrization, then having the tubercular form in and around the cicatrix, and the nodular growths undergoing cancerous ulceration. Recurrent cancer often runs its course more rapidly than the original growth, but it is said to be less painful and exhaustive.

The operation of excision is still justifiable, even to the third or fourth reappearance of cancer, in order to relieve suffering; provided the constitutional power of the patient seem sufficient to sustain life. I thus removed with some advantage a large tubercular cancerous cicatrix, and subsequently the whole of the axillary glands in a bunch, from a lady, whose breast I had previously completely excised; but after she had again enjoyed a temporary respite, the disease returned a second time, in the form of a nodular shield over the pectoral muscle, and when last I heard of her she was in a dying state.

*OPERATION OF AMPUTATION OF THE BREAST*.—Whatever may be the disease, whether a cancerous or non-malignant tumour; removal of the breast is performed in the following manner. The patient lying down,

and chloroform having been administered; an assistant holds the arm away from the affected breast, sufficiently to put the pectoralis muscle on the stretch, and define the breast on its axillary border. The Surgeon introduces a breast-knife on the axillary aspect of the breast, and makes a semi-elliptical incision below the nipple, varying in its extent according to the size of the tumour; this incision is made first, that its course shall not be obscured by blood trickling down from above. A corresponding incision is then made above the nipple, thus including the nipple and an elliptical portion of integument. The portion removed is small compared with the size of the tumour, but the integument remaining as a bag after operation, contracts eventually so as not to be superfluous. The breast is then dissected out from below upwards, the knife being carried slopingly around the organ down to the fibres of the pectoralis, along the axillary aspect of this muscle, and thence upwards under the tumour, to meet the upper incision. (Fig. 396.) Care should be taken not to make a button-

FIG. 396.

hole in the skin; a blemish which may be avoided by directing the edge of the knife towards the tumour, in detaching it from the integument, below and above.

A *cancerous* breast must be removed more extensively than when it is the seat of non-malignant tumour. The incisions should be carried so as to include any apparently affected portion of integument; and prolonged upwards towards the axilla when necessary, to allow the removal of any affected glands. In removing the tumour, the dissection should be carried wide of the disease and fairly into apparently sound tissue around, in order to completely extirpate the diseased mass. It may be more convenient in concluding the operation, to extend the axillary junction of the incisions, so as to reach any diseased glands; their connexion with the breast will enable the Surgeon to drag them out of the axilla, when they can be readily detached by successive touches with the knife. If the glands be removed after the breast, they may be seized with artery-forceps or a vulsellum, and dissected out. The operation-wound should be carefully examined, to see that no part of the gland or affected portion of cellular texture remain behind.

Arteries bleeding must be tied or twisted; they are principally situated towards the axillary aspect of the wound. If the tumour removed be non-malignant, only one or two vessels may have to be secured;

removal of a malignant tumour will probably necessitate the ligature or torsion of numerous and large-sized arterial branches, which are supplied to this more active form of growth; and venous hæmorrhage may require control. Cold ablution will generally arrest any oozing hæmorrhage, arterial or venous. The lips of the wound should then be brought together by a few points of suture; and the support of two or three strips of plaster with a compress of lint and a bandage, will prevent any subcutaneous hæmorrhage and bagging in the loose integument. Primary union sometimes takes place, and in a few days; but more frequently this union is spurious, and the wound opens up partially at least, with suppuration, and heals by granulation. Secondary hæmorrhage may necessitate a re-opening of the wound, and the application of ligatures. Eventually a sound, puckered cicatrix is presented; or perhaps a recurrent form of growth, when the original tumour was malignant.

FUNCTIONAL DISORDERS OF THE BREAST.—(1) *Abnormal secretion of milk*.—This disorder relates to the age of the woman and is also unassociated with pregnancy. The breasts of old women have been known to secrete milk; and it has formed at a very early age,—eight years. In some women, reputed virgins, the breasts have secreted a troublesome quantity of milk; and I have seen the lacteal secretion excited in a woman nearly fifty years of age, after sexual intercourse; she having borne eleven children.

(2) *Excessive lacteal secretion*—or *Galactorrhœa*.—The milk may be constantly dribbling away; or the secretion may continue after weaning suddenly, or at the termination of a proper period. This undue secretion is suppressed most effectually by the application of the extract of belladonna, spread thickly on lint, and placed over the whole breast or both breasts. Sedatives and tonics have also some degree of beneficial influence in arresting the secretion.

(3) *Deficient lacteal secretion*—or *Agalactia*—depends, either upon an organic imperfection of the gland, or on constitutional causes. The secretion will probably be excited by the application of the leaves of the castor-oil plant to the breast, by warmth and moisture, and by the stimulus of the act of suckling.

(4) *Congestion with Milk*.—This state seems to depend on a secretion of the more solid constituents of the milk, without the serous; thus favouring an accumulation of thick milk in the lactiferous duct, instead of the escape of the secretion being facilitated by a due admixture of fluid. The breast acquires an enormous size, and a stony hardness, resembling scirrhus. But the sudden appearance of this large tumour, and its occurrence during lactation, probably when this function first commences after parturition; are sufficiently diagnostic.

Lacteal congestion of the breast proceeds very slowly, and generally terminates in inflammation and abscess.

This affection is usually confined to one breast; and the gland having regained a healthy condition, performs its function healthily after a subsequent parturition.

The *treatment* consists in strapping, and the application of an ointment of iodide of potassium or iodide of lead; gentle aperients and tonics.

DISEASES OF THE MALE BREAST.—The mammary gland in the male exists in a rudimentary state; occasionally only some development of glandular structure taking place. Soon after birth, the organ becomes

tumid, and a slight secretion forms within the ducts. This naturally ceases, or may require repressive treatment. At puberty, the gland again enlarges, is painful for a few days, and then subsides. Irritation at this time may induce inflammation and abscess.

*Hypertrophy* of one or both breasts sometimes occurs in men of delicate constitution; the glands enlarging sufficiently to resemble the bosoms of young girls. *Treatment* of any such natural conformation will scarcely succeed in reducing this annoyance.

*Tumours*, of the same species as those in the female breast, occasionally form in the male breast. Cancer is the most frequent growth, and it occurs generally between forty and fifty years of age. The *treatment* of morbid growths presents nothing peculiar. Amputation of the breast is performed in the same way as for the removal of the female breast, but the operation in the male is less extensive.

ANOMALIES OF DEVELOPMENT, IN THE FEMALE AND THE MALE BREAST.—

(1) *Absence* of the Breast is recorded both by Sir A. Cooper and Froriep. Congenital deficiency of the Nipple has also been met with.

(2) Supernumerary Breasts are of more frequent occurrence, though rare. Most frequently, one supernumerary gland has been found; sometimes, two such glands; rarely, three; constituting, with the normal glands, five mammae. The situations of an abnormal mamma are remarkable; usually contiguous to the natural breast, and where four breasts have been developed, they have ranged in parallel pairs, one above the other on either side of the thorax. But an extra breast has been found in the axilla, on the back, on the abdomen, in the groin, or on the outer part of the thigh. These glands, thus oddly situated, have been known to secrete milk. Supernumerary *Nipples* also sometimes occur; two to each natural breast, both nipples communicating with the gland and passing milk. Several extra nipples have been developed on one breast.

The *male* breast is liable to similar developmental anomalies. Thus, four nipples have been seen. Deficiency of one or both nipples seems to be unknown.

## THE ABDOMEN.

### CHAPTER LI.

#### INJURIES OF ABDOMINAL PARIETES, AND VISCERA.

INJURIES of the Abdomen are of almost equal concern to the Civil and Military Surgeon. Their leading practical distinctions are as follow.

CONTUSION OF THE ABDOMINAL PARIETES.—The extent of structural disorganization produced by contusion varies considerably; the abdominal muscles being lacerated possibly, while the skin remains unbroken. The ordinary appearances of Bruise are presented, in most cases, and the usual symptoms of shock in a greater or less degree.

The *cause* of contusion may be various occasions of external violence—such as a blow or kick. Shock may either soon prove fatal or pass off;

and the bruise may gradually disappear, or be succeeded by abscess, or by peritonitis and thence a fatal termination. After recovery, the abdominal wall sometimes becomes atrophied at the seat of injury, predisposing to the occurrence of ventral hernia.

The *treatment* has reference to the recovery from Shock, by a moderate administration of stimulants; followed by the ordinary topical applications to a bruised part, coupled with rest.

*Wounds* of the Abdominal Walls, differ in no particular from the same injuries elsewhere, and the treatment must be conducted on ordinary principles.

*Abscess* sometimes forms in the abdominal parietes, and may spread extensively. It arises usually from contusion or other injury; but I have seen wide-spread parietal suppuration proceed from the irritation of a foreign body—a bean, impacted in the vermiform appendix of the cæcum, which lay in contact with the abdominal wall, apparently as a spontaneous effort of elimination. Carbuncular abscess also I have known to occur in the abdominal wall. *Treatment* of abscess in this situation presents nothing peculiar.

**INJURIES IMPLICATING THE ABDOMINAL VISCERA.**—The *general symptoms* of any such injury are those of Shock—severe and prolonged, coupled with the collapse arising from internal hæmorrhage. The pallidity of countenance and anxious expression, the coldness of surface, and thready feeble pulse, are sufficiently characteristic symptoms. With extensive internal hæmorrhage there may be perceptible dulness on percussion.

*Special* symptoms proceed from injury of different abdominal viscera; they are somewhat diagnostic of the organ implicated, but depend also on the causes of such injury.

The *causes* in question, are rupture from contusion, and penetrating wounds of the abdomen. *Contusion* is necessarily occasioned by severe external violence; the passage of a cart-wheel across the abdomen, or compression between the buffers of two railway carriages, known as Buffer-accidents; and in Military Practice, the brushing action of a wind contusion, or the direct pounding of a spent cannon-ball. Rupture of any one of the viscera, and extensive internal hæmorrhage, are not necessarily attended with any mark of contusion or bruise, as an outward sign of this internal injury. An abundant layer of fat in the abdominal wall, combined with thick clothing, seem to form a buffer of yielding resistance, which may prevent the production of a bruise. In one such case, a stout female, who had been brutally kicked in the abdomen by her paramour, died in a few hours from collapse. I found a large collection of black clotted blood in the abdominal cavity, but not a trace of discoloration in the integument. *Penetrating Wounds* are commonly produced by a stab, or a pitchfork accident; and in Military Practice, by a sword-cut or bayonet-thrust.

*Rupture, or Penetrating Wound, of Different Viscera.*—*The stomach.*—The diagnostic symptoms are; vomiting of blood, with perhaps the escape of some of the contents of the stomach in the case of a wound. But the stomach has been *ruptured*, almost completely across near the pylorus, and no blood appeared in the vomited matters. The situation and depth of a *wound* will help to determine the diagnosis.

*The Bowels.*—Similar symptoms are diagnostic; the passage of blood in the stools, and the escape of fæcal matter through a wound. Extravasation of fæcal matter into the abdominal cavity is attended with instant,

excruciating pain, radiating over the whole abdomen from the seat of injury, and extreme collapse. But a small wound of the intestine may not allow of extravasation; the mucous membrane protruding through the muscular coat and occluding the aperture, while the equable pressure of the abdominal viscera against each other prevents any escape from an intervening wound. Subsequently, the speedy effusion of plastic lymph tends to close the aperture. The absence of the characteristic pain and collapse—as symptoms of feculent extravasation, is, therefore, no conclusive evidence that the bowel is neither ruptured nor wounded. Emphysema of the abdominal wall may arise from the escape of flatus through an intestinal aperture, into the sub-peritoneal cellular tissue. Commencing, usually, in one or the other flank, the peculiar, pitting, crepitating swelling extends forwards around the abdominal parietes, and upwards towards the axilla. This symptom is the result alike of rupture or wound.

*Liver.*—Owing to the highly vascular nature of this organ, rupture or wound of its substance is attended with copious hæmorrhage, and proportionate collapse. A bilious discharge distinguishes wound of the liver. Recovery from either injury has been known to occur in some cases; but followed by peritonitis, jaundice, or, as Bernard has shown, saccharine diabetes. The *gall-bladder* alone may be the seat of injury, and rupture or wound seems to have been almost always fatal.

The *spleen*—a fragile and highly vascular organ—is perhaps equally liable with the liver to rupture, and wound may occur; either form of injury is attended with severe internal hæmorrhage and collapse, and both are proportionately fatal.

The *kidneys* are liable to rupture or wound. Frequent micturition of bloody urine is the diagnostic symptom; although the secretion of urine may be suppressed by complete structural disorganization of the kidney, and thus, the absence of this symptom is no assurance that the kidney is uninjured. The escape of urine through a wound will at once indicate the nature of this injury. Any injury to the kidney may induce nephritis.

The *Diaphragm* is most frequently ruptured in connexion with other organs; it may also be penetrated by a stab-wound, by gunshot injury, or by a fractured rib without any external wound. The visceral complication is the fatal element in these diaphragmatic injuries. Hernial protrusion of the abdominal viscera into the thoracic cavity may take place; or occlusion of the gap by the formation of a false membrane is a possibly reparative issue.

*Penetrating Wounds, not involving any viscus*—are distinguished simply by the absence of any symptoms of visceral complication. The escape of a small quantity of reddish serous fluid is the only positive diagnostic sign. Gentle examination with the finger will best and most safely ascertain the fact of penetration.

*Protrusion of Viscera*—and *with Wound of Viscera*.—The former condition is a visceral implication of dangerous character, the latter condition is positively perilous. Both owe their vital significance to the great risk of peritonitis; any extravasation of blood or the contents of certain viscera, increasing this liability.

Protrusion of the stomach, intestine, mesentery, or omentum, may be recognised by the appearances of the protruded mass. Its size is always large as compared with the aperture from which it emerges; and the margin of the opening constricting the protruded portion of viscus, a neck

or peduncle is formed, which is overlaid and concealed by the mass. The aperture and peduncle can be easily discovered by gently raising the protrusion with the fingers. At first, of a bright red colour and glistening peritoneal aspect, the mass soon becomes dull-looking and purple from congestion, and afterwards black and flaccid, as gangrene supervenes.

Wound of a protruded intestine is denoted by the escape of fecal matter and flatus; the characters of the wound also are peculiar, and vary according to its size. A puncture, or an incision two or three lines in length, is attended with eversion or prolapsus of the mucous membrane; which, closing the aperture, prevents the escape of feculent matter. An incision beyond four lines in length, evinces some tendency to protrusion of the mucous membrane in the form of a lip over the margin of the cut; but thus allowing the discharge of feculent matter.

*Consequences, and Prognosis.*—All Injuries of the Abdomen implicating the viscera, whether by Rupture or Wound, are liable, in some degree, to be followed by Peritonitis. Penetrating Wounds of the abdominal cavity have also this liability. But if implicating the stomach or intestine, in particular, the risk is greater; and if attended with the escape of the contents of these viscera into the peritoneal cavity, the danger reaches its maximum. On the other hand, all such injuries have a notable tendency to reparation, by primary adhesive union, and without the extravasation of intestinal or other matter. Certain remarkable cases of such reparation are on record. Thus, John Bell refers to the case of an extensive lacerated opening of the abdomen, in the person of a peasant boy who had been gored by a bull. The intestines—unwounded—protruded, and were replaced. The poor lad came the next day on foot three miles from his village, carrying in the skirts of his shirt and in his hands, a great bundle of intestines which had again protruded; they were again returned, the wound was neatly sewed, and recovery ensued. A madman stabbed himself with eighteen deep wounds in the abdomen, with a long and sharp-pointed knife; eight of the wounds penetrated the cavity of the abdomen, and touched the stomach and intestines, as shown by the vomiting of blood and its passage by stool. Yet the man entirely recovered in two short months. In another paroxysm of madness, eighteen months after this recovery, he threw himself from a high window and died upon the spot. Post-mortem examination revealed the important series of facts;—that, the liver, having been wounded, had adhered in its middle lobe to the inner surface of the peritoneum; the jejunum having been wounded, just below the stomach by an incision half an inch in length, across the gut, this portion of intestine lying deep was not pressed against the inner surface of the abdomen but remained in close contact with a contiguous turn of the jejunum—the two turns of intestine had adhered together, one showing the scar of the wound, the other being untouched; the right side of the colon, wounded by an incision an inch long, had united and adhered to the inner surface of the peritoneum by about a score of long thread-like tags of false membrane, issuing from the inner surface of one of the largest scars in the abdomen.

*TREATMENT.*—*Rupture* of any abdominal viscus—without wound of the abdominal wall, presents only two indications of treatment; restoration from collapse; and the restriction of extravasation, whether of blood or feculent matter, in order to prevent the supervention of Peritonitis. The one indication may be fulfilled by a judicious administration of stimulants, with other measures to induce reaction; the other may perhaps be ac-

complished by rest and sedatives. Opium in grain doses, or the liquor opii sedativus should be given every four hours, so as to keep the patient under its influence, hydrocyanic acid and potash to allay sickness; while the diet must be restricted to spoonful of cold beef-tea, with barley-water and ice, and no aperient medicine given for some days. A mild enema of gruel and castor oil will then be advisable.

*Penetrating wound of the Abdomen*,—not involving any viscus, should be closed in the ordinary manner of a wound in a loose and moveable part. A few points of suture must be used to steady the edges of the integument in apposition, aided by a suitable position to relax the abdominal muscles; but the precaution of a compress and bandage will be requisite as a support, to prevent the risk of visceral protrusion.

*Protrusion of any viscus*, commonly a portion of intestine or omentum, must be met by early reduction, before signs of strangulation have supervened. Relaxation of the abdominal muscles by position, and gentle manipulative pressure, is the rule to be observed. Pedunculated constriction of the protruded mass, should be overcome by slightly enlarging the aperture with a probe-pointed bistoury or hernia-knife. In returning the part, the direction of pressure should be towards the abdominal cavity through the aperture; lest, otherwise, the protrusion be slipped between the muscles, leaving the neck unreduced. Having entirely returned the part into the abdomen, the finger should not follow it further; the gut or omentum may remain more safely placed near the aperture, than in the event of sloughing there shall be a free vent for the discharge. An inflamed state of the protrusion does not contra-indicate its reduction; but gangrene of the intestine must be treated on a different principle,—an incision to discharge the contents of the protruded portion, and the formation of an artificial anus. Gangrenous omentum should be removed by excision.

*Wound of the intestine* modifies the treatment, according to the circumstance of the bowel being protruded, or not. Wound of the intestine *without protrusion* is out of reach; and the discharge of fecal matter must be facilitated. Accordingly, the patient should be laid in such position that the contents of the intestine may escape through the external wound in the abdominal wall; lying on the injured side may offer the most dependent position to the opening, or the recumbent attitude with the knees drawn up may best facilitate the discharge from a wound near the umbilicus. Wound of the intestine, *with protrusion*, is a condition respecting the treatment of which surgical authorities have held a difference of opinion. Closure of the wound with sutures, and reduction of the protruded portion of intestine just into the cavity of the abdomen, constitutes the plan of treatment generally applicable. The sutures, according to Travers' observations on animals, soon become coated over with a layer of lymph, and ulceration taking place inwards, they are eventually detached and fall into the intestinal canal; while the line of incision uniting by adhesion, leaves a firm cicatrix. For this purpose, it is necessary to bring the peritoneal margins into contact, as the source of adhesion. The needle used should be a fine round needle, and the sutures, fine round sewing silk; the whole thickness of the gut should be brought together, into even apposition, and the sutures clipped off close to the knot. When returned into the abdomen, the gut is left near the external aperture, to allow of free discharge in the event of sloughing. The abdominal wound, if extensive, may be partially closed by suture; leaving a dependent opening.

Reduction of the protruded portion, just into the abdomen, without closure of the wound in the gut, and so that the two apertures, intestinal and parietal, shall correspond and lie in contact; constitutes the other plan of treatment which has been recommended by some Surgeons of experience. Adhesion taking place between the two apertures, an artificial anus is formed. The alleged advantages of this procedure are; the absence of sutures—as foreign bodies, and the prevention of feculent extravasation incident to the mechanical closure of an intestinal wound by sutures. The mechanical efficiency of sutures is, however, now no longer a question. And, the obvious disadvantages of attempting to form an artificial anus are; the liability of feculent extravasation pending adhesion of the two apertures, subject also to alteration of their relative position; and the sad inconvenience of a permanent artificial anus in some part of the abdominal parietes. But an extensive and transverse wound, or a lacerated wound of the intestine, cannot be closed effectually by suture; it will almost inevitably reopen by sloughing, and a wound of intestine already gangrenous is unfit for reduction. In these *exceptional* conditions, the formation of an artificial anus will be expedient or unavoidable.

The *after-treatment* of wounded intestine, with or without protrusion, is the same as that of rupture. The principle being to prevent any peristaltic action which might disturb the process of reparative adhesion; opium should be administered to confine the bowels for a week, when a castor-oil enema may be given. During this period the diet should be sparing and exclusively fluid; subsequently, a small quantity only of light solid food must be gradually allowed for two or three weeks.

**TRAUMATIC PERITONITIS.**—Inflammation of the peritoneum consequent on injury, whether contusion or wound of the abdomen, is denoted by certain characteristic symptoms. Pain and great tenderness on the slightest pressure, spread from the seat of injury over the abdomen, accompanied with tympanitic distension and resonance on light percussion. A dry tongue, which soon becomes brown, constant nausea or vomiting, and obstinate constipation, are the main gastro-intestinal symptoms. The patient lies recumbent with his knees drawn up to relax the abdominal muscles, as the easiest position; he breathes entirely by the thorax, the abdomen scarcely moving with each respiration; and the expression of countenance is anxious, with perhaps a nipped appearance of the nose,—owing apparently to dilatation of the nostrils and a bleating action of the alar cartilages, in connexion with the short and hurried breathing. There may be frequent hiccough. The pulse is rapid, small, and hard, often feeling like a wire drawn under the finger; increasing rapidly to 100, 120 or more beats per minute, it becomes proportionately weak and irregular as vital power declines. Effusion taking place into the cavity of the peritoneum, resonance is exchanged for dulness on percussion; commencing in the flanks, where fluid first accumulates, and extending over the abdomen, as it increases in quantity. The lymph effused, commonly of greenish-yellow colour, may be fibrinous and plastic in character, fitted for adhesive reparation; or corpuscular and curdy, with an abundance of yellow serum, or sero-purulent fluid. The peritoneal surface is more or less injected, both in its visceral and parietal aspects; the tint of redness and form of vascularity varying in different parts of the membrane. Peritonitis after abdominal injury, begins usually in about twenty-four hours or from that to three days subsequently, and may run

its course rapidly, in either of these periods or longer, and sometimes assumes a *chronic* form. Plastic or reparative peritonitis is of a *sthenic* character; corpuscular, and especially purulent peritonitis is of an *asthenic* character, and speedily fatal.

*Treatment.*—The two general characters of Peritoneal inflammation indicates the plan of treatment. In both forms of the disease, the measures to be adopted consist; in topical blood-letting by means of leeches scattered over the surface of the abdomen, and warm fomentations; coupled with the administration of calomel and opium, in pill, every four or six hours, in order to prevent effusion beyond that requisite for adhesive reparation, and to promote absorption. But in proportion as the peritonitis is or becomes, *asthenic*, depletion must be moderated. Purgatives during the inflammatory stage are useless or injurious, the constipation depending on the paralyzing influence of inflammation over the peristaltic action of the intestines. In the case of wound of the bowel, this state of quiescence is necessary for reparation, and Nature's provision for that purpose. Beef-tea and other fluid food should be the only form of nourishment given during this period. Iced soda-water or barley-water seems to allay sickness, which may also be combated by hydrocyanic acid and potash, in draught, taken occasionally. At the end of about a week any feculent accumulation may be removed as a source of irritation, by the gentle action of an oleaginous enema. In *asthenic* peritonitis, the vital power must be sustained by wine, brandy and egg-mixture, or other stimulants, and light nourishing food.

*Chronic* peritonitis will require the continued influence of mercury, with blistering of the abdomen and mercurial ointment dressing, to remove the lingering effusion.

## CHAPTER LII.

### HERNIA.

HERNIA is a generic term, signifying the protrusion of any organ from its natural cavity; such protrusion occurring through a natural or accidental aperture. Thus we recognise Hernia of the brain, through an opening in the skull; of the lung, through an opening in the thoracic parietes; of a portion of intestine, omentum, or other abdominal organ, through an opening in the abdominal wall. The protruded part is covered by the integuments overlaying the aperture and course of the protrusion; and this structural condition may be said to distinguish Hernia from Prolapsus, which is simply an uncovered and exposed protrusion of any organ, as of the uterus or rectum. Hernia and Rupture are frequently used as synonymous terms; but the latter term would imply some breaking or laceration of the textures resisting at the seat of visceral protrusion, a lesion not necessarily connected with the production of Hernia.

Abdominal Hernia may be considered, in its General Pathology and Treatment; and that of the various Special Forms of such Herniæ.

GENERAL STRUCTURE OF ABDOMINAL HERNIA.—The Hernia consists of a peritoneal sac or pouch, with a corresponding portion of the abdominal parietes, and the sac-contents.

*Sac*.—The *sac* is a prolongation of the parietal layer of peritoneum, from the aperture in the abdominal parietes; but this prolongation is of two distinct kinds in relation to a Hernial protrusion. The *sac* may be produced in two ways; either by gradual protrusion and distension of the peritoneum under pressure of the protruding organ,—forming the ordinary, *acquired* hernial sac; or it may be a pre-existing vaginal process of peritoneum from malformation, into which an organ protruding, it thus becomes a hernial sac,—the *congenital* hernial sac. Both kinds of sacs are illustrated by inguinal herniæ.

A hernial *sac* consists of two portions; the *body* or dilated portion, the lowest part of which is sometimes named the fundus; and the *neck* or constricted portion, the abdominal opening into which is named the mouth of the sac. These distinctive terms are convenient for description, and practically important. The *sac* may be *absent* in certain structural conditions of hernia,—if the protruding organ be naturally, partially uncovered by peritoneum, as the cæcum or bladder; in hernia within the abdominal cavity, by protrusion through the mesentery or the meso-colon; in internal hernia, by the formation of an adventitious band of false membrane constricting a portion of intestine; from rupture of the sac by violence; or as the result of ulceration. On the other hand, *two* sacs may have formed, both having protruded through the same aperture, constituting a double hernia. One sac may be placed behind, or within the other. The *neck* of the sac may consist of *two* constricted portions; representing the natural anatomical condition of the surrounding parts,—as the external and internal abdominal rings, in complete, oblique inguinal hernia; or, the original neck may have slipped down with a fresh protrusion. I have thus seen *three* necks produced with corresponding constrictions, in a large scrotal omental hernia.

*Structural changes in the Sac*.—The size, shape, and textural condition of the peritoneal prolongation vary according to the period of its formation, in the *acquired* hernial sac. Commencing as a small, digital depression, it assumes the shape of a funnel, and then that of a finger of a glove. These forms are, however, somewhat dependent on the region in which the hernia is developed. At this early period, the entrance to the sac is larger than the body,—there is no true neck, and strangulation of the protruded organ cannot occur. At length, the sac reaching tissues of less resistance, undergoes dilatation and acquires a spherical shape; while the entrance becoming proportionately constricted and puckered, forms a neck of variable length and calibre, so that strangulation can occur. In this state, the sac may retain the originally thin, transparent texture of peritoneal membrane. Organization ensues, in both the body and neck of the sac, more particularly in the latter portion. The sub-serous cellular tissue is the principal seat of these textural changes. They consist in the formation of new blood-vessels, increasing the vascular appearance of the peritoneal surface, and a contractile induration of the cellular texture, attended with a marked diminution or disappearance of the fat, although the person be very fat. This textural transformation of the peritoneum is evinced by thickening and opacity of the sac, especially its neck. Contraction takes place to some extent, and even obliteration, when the hernial protrusion ceases. The peritoneal transformation acquires a fibrous and less vascular character, and the consequent induration may be almost cartilaginous. This is the state of an *old* hernial sac, and the

contraction is most notable when the sac has not been subject to hernial protrusion for some time. As affecting the neck, such change is at once perilous and curative; the one, by inducing strangulation, in the event of a hernial descent of any organ; the other, by leading to obliteration of the neck of the sac.

*Abdominal Parietes—and their Structural changes.*—The layers of different textures, constituting the abdominal parietes, through which a Hernial protrusion successively passes, form what are termed the *coverings* or investments of Hernia, in addition to the peritoneal sac. The aperture or apertures in the parietes, through which the Hernial protrusion occurs, corresponds to the neck of the sac. Both the aperture and the coverings undergo remarkable changes, which may almost or altogether efface the original anatomical characters of these parts; the sac also undergoing as thorough a transformation. The changes here referred to are partly mechanical, and partly textural. The hernial aperture becomes altered in shape, assuming a circular form, and enlarged, while its relative position is gradually displaced, and usually towards the middle line; two apertures thus forming one, as that of the abdominal rings in oblique inguinal hernia. The coverings of hernia gradually become stretched and loose, so that the skin appears redundant and wrinkled; when an old hernia is reduced. Textural changes consist in thickening and induration of the parietal aperture; and in the obliteration of the individual characters of the coverings, which become more or less fused into one. All these changes result from detrusion and pressure by the hernial protrusion, operating mechanically on the parts, or inducing textural degeneration and atrophy; or textural transformation may be the result of inflammatory adhesion,—consequent on strangulation, blows, or excessive manipulation. Thus then, the whole Pathology of Hernia must be regarded as a more important aspect of study than its pure Anatomy.

*Contents of the Sac—and their Structural changes.*—All the abdominal viscera are severally subject to Hernia, though not with equal frequency; the pancreas, it is said, alone excepted. The contents of a Hernial sac, therefore, vary considerably. They are usually the intestine or omentum conjointly or singly; the small intestine, particularly the ileum, more probably than any other abdominal viscus, owing to its long mesenteric attachment and its hanging near the abdominal apertures through which herniæ commonly occur,—namely, the inguinal and femoral rings. The quantity of intestine protruded may be small,—a knuckle of intestine, or not even the whole of its circumference, or it may extend to several feet in length. Omentum, varying in quantity, is folded together, or perhaps matted into a cylindrical mass; when unfolded, it has a triangular or fan-shape, the base being below and the apex upwards at the abdominal aperture. Old herniated omentum loses its peculiar ramified adipose cellular texture, and becomes consolidated; the veins assuming a somewhat varicose condition. Sometimes apertures form in it, through which a coil of intestine passing, strangulation may ensue within the sac. Cysts, occasionally, form in the omentum, and into which the intestine may slip. When intestine and omentum co-exist in the sac; usually the omentum descends in front, and may be found to enclose and conceal the intestine, on opening the sac. Occasionally, other viscera are herniated; the stomach, liver, spleen, cæcum, sigmoid flexure, or other portion of the colon, bladder, uterus, ovaries, or even the kidney. Serous fluid, of a yellowish or brownish colour, and transparent, is always found within a

hernial sac; but in very variable quantity. Usually only sufficient to lubricate the interior and contents of the sac; this fluid may be the principal constituent, amounting to several ounces, and distending the sac. It is thus copiously secreted when the sac is inflamed or the hernia strangulated, and most abundantly in inguinal herniæ.

Adventitious or false membranes, forming *adhesions*, are met with; either as the product of inflammation in strangulated hernia, or as the result of changes in old irreducible hernia. The situation, length, thickness and density of these adhesions, present many differences of appearance. Thus, adhesions may have formed between the interior of the sac and its contents, in the shape of uniting bands, or as bridles across the sac from one side to the other, imprisoning the contained viscera; or again, adhesions may have taken place between the latter, as between two coils of intestine, or between intestine and omentum. The neck of the sac is frequently the principal seat of adhesions. Parietal and visceral adhesions not unfrequently co-exist. *Recent* adhesions are soft and pliant; *old-standing* adhesions are firm and unyielding.

Adhesion of the omentum across the sac, so as to form a distinct sac or cyst below the visceral contents, and in which fluid accumulates; constitutes the condition known as *hydrocele of the hernial sac*. A considerable quantity of fluid may thus accumulate; Erichsen drew off nearly three pints of dark-brown fluid by tapping a cyst of this kind. It is a rare structural alteration in the hernial sac; one only having been noticed by Curling, one by Boyer, one by Lawrence, two by Pott, and two by Pelletan. To these I can add one, formed in another way; by closure of the neck of the sac, after reduction of a strangulated scrotal hernia by operation. The compress applied to secure reduction, speedily induced adhesion of the neck of the sac, and fluid accumulated below in the body of the sac; soon presenting the original appearance as if the hernia had returned. I tapped this scrotal sac, and drew off several ounces of brownish fluid which was not re-secreted. The case is fully reported in *The Lancet*.

Loose foreign bodies are occasionally found within the hernial sac; they are usually round, smooth and firm, varying in size from a pea to a chestnut, and single. They consist of a laminated fibrous envelope, with a central fatty nucleus; apparently one of the glandulæ epiploicæ detached, and encapsuled.

*Strangulation*.—The structural changes coincident with *strangulation* of the hernial protrusion, demand special notice. They relate to *adhesions*, the state of the *intestine*, or *omentum*, and of the *serous fluid* in point of its colour, consistence, and odour. *Adhesions* have already been described sufficiently; their situations, and their characters as *recent* adhesions compared with the old-standing adhesions of irreducible hernia. The following changes take place concurrently in the state of the serous fluid and intestine within the sac, and are notably important; the one as being an indication of the other. With strangulation of only a *few hours'* duration; the fluid is pale yellow, clear and bright, the intestine is simply *congested*, of a deep-red colour, and its texture elastic. With strangulation of *many hours'* existence; the fluid is dark-brown, but clear, and the intestine of a purple tint, but its texture still retains its elasticity. With strangulation of *long duration*, or after violent and protracted taxis; the fluid resembles a strong infusion of coffee, it is turbid, with blood and small coagula mingled; the intestine is dark purple shading to black, it

has lost its peritoneal brilliancy and become dull-looking, its texture is leathery, not resilient; infiltrated with blood, and often having flakes of lymph adherent to its surface. With turbid serum, of a dull brownish yellow colour, and mixed with blood, coagula, pus, flakes of lymph, and even fecal matter, in which state the odour of fæces is perceptible; the intestine is approaching to a *gangrenous* condition, or has already passed into *sphacelus*. With the escape of gas through serum, of the nature last described, bubbles are produced, and the intestine is *ruptured*.

In the natural course of unrelieved sphacelated hernia, the *sac* and *integumental* coverings become inflamed, infiltrated with serum and pus; crepitation ensues either by the escape of gas from the sac or its formation in the decomposing textures externally, and gangrene of the skin supervening, the slough separates, and an artificial anus is established. Simultaneously, firm adhesion takes place between the neck of the sac and the hernial aperture; thus preventing the escape of fecal matter backwards into the abdomen. If the hernial stricture were relieved at this or even an early stage of gangrenous intestine—and short of sphacelus, the intestine might not regain its vitality; the portion of bowel remaining nipped and marked as by a band constricting it. I have thus seen strangulation of only half the circumference of a portion of intestine, prove fatal after operation.

Omentum passes through similar changes of congestion and gangrene; and if unreduced, the sac and its coverings may slough, and the portion of omentum become detached, the patient making a good recovery.

*Peritonitis* coincident with strangulation, commences about the neck of the sac, and spreads over the abdomen. The pathological appearances are not peculiar; an injected peritoneal surface, with plastic lymph of greenish-yellow colour, agglutinating the intestines or overspreading them, and puriform serum accumulated in the cavity of the peritoneum.

**SITUATIONS OF HERNIA.**—The various apertures naturally existing in the abdominal parietes offer structural facilities for the protrusion of the viscera; while apertures accidentally existing as malformations, or formed by injury or disease, also favour the occurrence of Hernia.

Taking the former as the more common and normal, or anatomical situations of Hernia, they are; above Poupart's ligament—through the inguinal canal; below the ligament—through the femoral canal; through the several apertures of the pelvis;—in front, through the obturator or thyroid foramen; through the arch of the pubes in the perinæum; below,—into the labium pudendi; by the side of the vagina; behind,—through the ischiatic notch; through the umbilical aperture; or at other parts of the abdominal wall; in ventral, epigastric, and lumbar Herniæ; and through the diaphragm.

**NAMES OF HERNIE.**—Distinctive names are given to abdominal herniæ; according to their anatomical situation; the viscus protruded; the period of life at which the hernial sac is formed; the stage of protrusion; and the pathological condition of the herniæ. Thus we recognise by their *situation*; Inguinal hernia, Femoral or Crural hernia, Obturator or Thyroid hernia, Perineal hernia, Pudendal hernia, Vaginal hernia, Ischiatic hernia, Umbilical hernia, Ventral hernia—at the linea alba, or the linea semilunaris, Epigastric hernia, Lumbar hernia, Diaphragmatic hernia. The *protruded viscus* gives names; Intestinal hernia or enterocele, Omental hernia or epiplocele, their combination being Entero-epiplocele; hernia of the stomach or gastrocele; of the bladder or cystocele. *Congenital*

hernia, and its variety, *Infantile* or *Encysted* hernia, relate to the formation of the hernial sac by the persistent patency, from birth, of the vaginal process or sheath of peritoneum in the tunica vaginalis testis; the one condition signifying complete patency of this sheath; the other, its closure at the abdominal orifice, leaving the sheath open below, and into which the hernial sac descending, the tunica vaginalis encloses the sac—forming an encysted hernia. *Complete* and *Incomplete* hernia are terms having reference to the stage of protrusion; inguinal hernia incomplete, or within the canal, is named bubonocele, and when complete, scrotal hernia in the male, labial in the female. The pathological condition of hernia gives rise to highly important practical distinctions; *reducible* hernia, *irreducible* hernia, *incarcerated* and *strangulated* herniæ.

CAUSES.—The formation of Hernia depends upon a weakness of some point of the abdominal or pelvic wall, and thus an insufficient resistance to the protruding pressure of the viscera, as subject to the compressing action of the abdominal muscles and diaphragm. The causes of hernia are, therefore, of two kinds, predisposing and exciting.

(1) *Predisposing* causes.—*Structural* predisposition consists in the natural existence of the various anatomical apertures in the abdominal and pelvic wall, corresponding to the normal situations of Hernia; and congenital malformation is predisposing, chiefly as connected with congenital and infantile inguinal hernia; or the predisposition may arise quite accidentally, from injury—by contusion, or by distension of the abdomen during pregnancy or dropsy, or as the result of disease—by abscess or other weakening disorganization of some part of the abdominal wall. *Laxity* of some of the abdominal viscera might be reckoned among structurally predisposing conditions—*e.g.*, the ileum having a long mesenteric attachment, and hanging near the inguinal and femoral rings; the omentum also loosely hanging as a sort of abdominal apron, when not tucked up to the right as in some cases.

*General* predisposition relates to sex, age, hereditary influence, and occupation.

*Males* are far more liable to hernia than females. Mr. Kingdon estimates the proportion at 2 males to 1 female, for all ages and including every form of hernia. Out of a gross total of 96,886 applicants for trusses at the City-of-London Truss Society; 78,394 were males; 18,492 females. In relation to the *population*, the frequency of hernia is uncertain; the proportion has been estimated as high as 1 in 8 of the male inhabitants of the whole kingdom, and 1 in 5 of the inhabitants of one district. In France, Malgaigne estimated the proportion as being 1 man in 13, and 1 woman in 52. In relation to the *situation* of hernia; males are more subject to inguinal, females, to femoral and umbilical hernia.

*Age*.—Differences of opinion prevail as to the liability of period of life; according to Malgaigne, hernia is less frequent before the age of 35 years than after that period; Birkett affirms, that taking all varieties of hernia in both sexes, the majority are developed before 35 years of age. Thus, by reference to statistics; out of 2343 cases recorded by Malgaigne (*L'Union Médicale*, 1854), 555, or 23·6 per cent. were under 35 years of age, and 1788, or 76·4 per cent. above that age. On the contrary, out of 9296 cases recorded by Mr. Kingdon; 5659, or 60·8 per cent., had commenced before the age of 35 years, and 3637, or 39·2 per cent., after that age. The great discrepancy between these results is easily explained; the one series records the ages of the patients at the time of observation,

the other had reference to the ages when the hernia was first noticed—the essential element in estimating the relation of period of life to hernial protrusion.

*Age in relation to Sex.*—The proportion between males and females varies considerably at different periods of life, owing to congenital predisposition. According to Mr. Kingdon's statistics for 1860–1; in the first 5 years of life, the proportion was 1409 males and only 107 females; while in the 5 years from 25 to 30 years of age, the ratio had changed to 846 males against 207 females.

*Hereditary influence.*—The children of ruptured parents are frequently affected in like manner. Both sexes evince an equal tendency to be thus influenced; the proportion being about 34 per cent. This influence, paternal, maternal, or from both parents, is manifested mostly in infants under 1 year; the proportion being about 12 per cent. of the whole number under that age. This fact is referable, apparently, to an arrested closure of the ventral orifice of the vaginal process of peritoneum, and the obliteration of that sheath; and also to an abnormal elongation of the mesentery; both of which, as congenital structural conditions, are very probably much influenced by hereditary conformation.

*Occupation.*—All persons are liable to hernia; but the labouring class is most subject, seemingly, however, irrespective of any particular trade or occupation. Comparing the twenty-five largest classes of occupation, arranged in the order of their magnitude from the census of 1851, with the numbers of each class who applied to the Truss Society during three successive years; Mr. Kingdon finds that the number of such patients bears a direct proportion to the numerical magnitude of the classes to which they respectively belong, and not to the severity of the toil.

(2) *Exciting Causes.*—Any sudden and forcible diminution in the capacity of the abdominal cavity, resulting from the compressing contraction of the abdominal muscles, may be productive of hernia. Hence, it often happens in strained attitudes and postures of the body during the effort of any violent muscular exertion; and in particular, hard riding on horseback, violent running or jumping, acrobat performances and ballet dancing, high pitch singing, violent coughing, straining defecation or micturition in connexion with constipation or stricture, and in difficult parturition. The production of hernia may be sudden, but perhaps more commonly it is of gradual formation.

*REDUCIBLE HERNIA.*—*Symptoms.*—A soft compressible swelling or lump appears at some part of the abdominal parietes; commonly, in the groin just above the middle of Poupart's ligament—at the internal abdominal ring; or below the ligament internally, and corresponding to the saphenous opening. This tumour increases in size when the patient stands, and still more so when he coughs, and the latter act communicates an impulse more or less perceptible to the hand when placed upon the tumour; on the contrary, it diminishes in the recumbent posture, and can be made to disappear by gentle compressive manipulation in the direction of protrusion,—the contents of the hernial sac, with sometimes the sac itself, being returned into the abdomen, whence this procedure is denominated the *reduction* of Hernia. The tumour will probably reappear, when the patient stands upright, and the pressure is removed from the hernial aperture. There is no pain or other sign of inflammation in connexion with a reducible hernial tumour.

*Intestinal hernia, —enterocele, and omental hernia. —epiplocele, present*

tumours having distinctive characters and which are tolerably perceptible. Enterocele is soft, compressible and elastic, uniform and globular; it yields a distinct and distending impulse on coughing, and a gurgling noise as it returns, suddenly, into the abdomen. Epiplocele is harder, inelastic, and lobulated; yields a less distinct and a solid impulse on coughing, and returns, slowly, as a lump into the abdomen. *Entero-epiplocele* presents a tumour of mixed characters, and this is the more frequent condition of hernia; or examination fails to detect the visceral nature of the protrusion,—whether it be intestine, omentum, or both. An accumulation of fluid in the hernial sac, will disguise the visceral nature of its contents, and simulate intestine. Thus, in one case of apparently scrotal enterocele; I found, by operation, only half the diameter of a knuckle of small intestine protruded at the external abdominal ring, and the sac distended with serous fluid.

Various kinds of swelling in the regions of Hernia simulate that disease; but their *diagnosis* will be more usefully noticed in describing Special Herniæ.

*Treatment*.—This may be mechanical and palliative, or operative and curative.

(1) *Mechanical* treatment consists, in the reduction or return of hernia—by the manipulative procedure technically named the *Taxis*; and the prevention of its return,—by means of a suitably fitting support or Truss. The constant wearing of such an appliance may, perhaps, lead to obliteration of the neck of the sac, and a radical cure.

*Taxis*.—Reduction is effected by placing the patient in the recumbent position, relaxing the abdominal muscles by bending the thigh upon the abdomen; and then gently compressing the tumour with the fingers, back in the direction of protrusion.

*Truss*.—The characteristic qualities of a Truss are; its lightness, firmness, elasticity, suitable adaptation to the configuration of the wearer, and sufficient strength of spring to prevent the escape of the rupture from the abdomen. The instrument consists of a pad or cushion attached to a metallic spring, with straps, so arranged that its movement during the varied postures of the body may be restrained. Bearing in mind these essential elements of truss construction, a detailed description of the various forms of Trusses employed for the different situations of hernial protrusion, will be far better understood in connexion with Special Herniæ. The circular spring truss is, generally, the most suitable form. The names of trusses, more or less in common use, are; Salmon and Ody's self-adjusting truss, which has a pad revolving on a ball and socket; the Maidstone truss, with a sliding pad; Edwards' truss, with a revolving and sliding pad; Adams' graduated pressure truss; Arnott's graduated pressure truss; Coles' truss, with a spiral spring acting on the pad; Tod's truss, affording more effectual compression at the internal abdominal ring; Newson's wire truss, affording more effectual security against displacement; Egg's truss, which requires no fastening; the Moc-Main lever truss; the Tail-padded truss; and Bourjeaud's elastic india-rubber belt and pad, which may be more conveniently used for children.

A truss having been applied, it should be tested, by desiring the patient to sit on the edge of a chair, open his legs widely, bending the body forwards, and cough several times. If, in that posture, and with such effort, the hernia still remains up, without any tendency to slip down behind the pad; the truss assuredly fits well, and will prove effectual

under all ordinary circumstances. The Truss should be worn daily, and taken off only at night. Irritation consequent on continued pressure of the pad, may be relieved by washing the skin with spirit lotion, and substituting an elastic air-cushion for a while.

(2) *Operations for Radical Cure.*—The principle implied by the cure of Hernia, is the obliteration of the sac or its neck.

*Compression* of the whole neck of the sac by means of a well-fitting truss, has led to its adhesive obliteration, in hernia at an early period of life; the cure also being safe and remaining permanent. But this procedure must be continued for a considerable time, at least two years; and then, as a precautionary measure, prolonged for two years more.

Various *operative* procedures have been devised for the radical cure of hernia, most of which having justly become obsolete may be here omitted. The object being to obliterate the sac or its neck; this may be accomplished, either by simple invagination of the sac and integument into the neck, the invaginated portion acting as a plug and closing the neck by adhesion between it and the hernial aperture; or, in addition to invagination, by the approximation and adhesion of the surrounding textures, thus producing further consolidation. Three operations are practised, in accordance with these two methods; Gerdy's and Wurtzer's operations are simply *invaginations*; Mr. John Wood's operation is, in addition, a *compression of the boundaries* of the hernial canal in its entire length.

The performance of these operations will be described in connexion with the treatment of *inguinal* and *femoral* herniæ.

The results of any such occluding operation are uncertain; there is some risk to life, unwarrantable perhaps in order to remedy the purely mechanical inconvenience of a reducible hernia; and greater uncertainty as to a permanently successful result, without the inconvenience of continuing to wear a truss for protection against a relapse.

**IRREDUCIBLE HERNIA.**—This condition signifies simply that the contents of a hernial sac cannot be reduced or returned, entirely at least, into the abdomen; but there is no obstruction to the passage of feces through the intestinal portion, nor to the circulation,—the hernia is not incarcerated nor strangulated. The contents are, generally, for the most part omental, with intestine and mesentery, and the hernia is usually long-standing and of large size; the gut perhaps slipping up occasionally, leaving the omentum unreduced. The largest irreducible hernia I have ever seen was in the scrotum of a man in the Millbank Penitentiary—the scrotum, on the right side, hung down nearly to the knee; and Mr. Birkett met with a double scrotal hernia in a bricklayer, aged fifty-five years, where the tumour reached down very nearly to a level with the patellæ, and its circumference measured thirty inches. The left hernial tumour was the larger, although it had existed only about three years, whilst the right had been there twelve.

*Causes.*—Enlargement of the omentum or mesentery, as by an accumulation of fat, may lead to an irreducible condition of hernia; although the portion protruding through the mouth of the sac may be small. Adhesions between the sac and its contents, or adhesion of the neck of the sac; may severally produce the same result. Contraction of the neck is sometimes thus occasioned, or an hour-glass contraction of the sac; either of which alterations of shape will further prevent reduction. Hernia of the cæcum or of the bladder are irreducible, owing to their peculiar anatomical conditions.

*Consequences.*—The increasing size and weight of an irreducible hernia entails proportionate mechanical inconvenience, coupled with occasional dragging pains, nausea, or vomiting, and colicky, disordered action of the bowels. Besides all this inherent discomfort, the hernial contents are liable to the accidental peril of inflammation, from injury by blows or other external violence, or from strangulation, on any occasion of unusual exertion. Omental hernia is less dangerous than intestinal protrusion, but there is always the risk of a piece of bowel slipping down and inducing strangulation.

*Treatment.*—The indications are twofold; to prevent any increase of size, by additional protrusion; and the peril of inflammation thence arising, or from external violence. The support of a truss, with a large hollow pad for the protection of the hernia, will best fulfil these indications; but a very large hernia must be supported by means of a suspensory bag. Any violent exertion, or constipation, should be avoided as much as possible.

Reduction can sometimes be accomplished by diminishing the contents of the hernial sac. Mr. Bransby Cooper recommended a gradual course of treatment—confinement of the patient to bed for several weeks on low diet, with the continued application of ice to the tumour; and if it contain much omentum, the administration of small doses of blue pill and tartar emetic, in order to promote absorption of the fat. This plan has proved successful in some cases. Suspending the patient with his head downwards may induce the hernial contents to return into the abdomen. But the contents of an old hernia, when returned into the abdomen, may be a source of so much irritation, that any attempt at reduction, and especially by a mechanical and suddenly effective proceeding, should always be well considered.

*Inflamed Irreducible Hernia*—closely resembles strangulation, in its symptoms and treatment. If arising from any injury to the tumour, from a blow or other external violence; the peritonitis commencing in and spreading from the sac, may be subdued by rest and leeches, enemata and abstinence from food, with perhaps the administration of calomel and opium.

*Incarcerated Hernia.*—This term is intended to signify such imprisonment of the contents of a Hernia,—itself irreducible, as shall obstruct the passage of fæces through the intestinal portion; but there is no impediment to the circulation—no strangulation.

The *Symptoms* are, some increase of size and painful sense of weight, in the tumour, without any tenderness or pain about the neck of the hernial sac; and this local condition is accompanied with constipation, and nausea or even vomiting. These symptoms have a chronic character, unlike those of strangulation.

*Causes.*—An accumulation of feculent matter or flatus in the fold of protruding intestine; and often preceded by constipation and the swallowing of hard, indigestible food. It occurs commonly in elderly persons, with large abdominal capacity.

*Treatment.*—Excitation of the peristaltic action of the intestine is the natural indication, as to the kind of remedial measures for removal of the obstruction; the patient remaining, of course, in the recumbent position. Aperient enemata answer best, and in particular a colocynth injection; purgatives administered by the mouth may operate beneficially, in the absence of vomiting. When some relief has been thus obtained, reduc-

tion of the intestinal contents may be advantageously attempted; any previous manipulation of the accumulation might tend to increase it.

**STRANGULATED HERNIA.**—Strangulation of a Hernia is said to have occurred when the protruded viscera—intestine, omentum, or both, are so constricted; that, in addition to functional obstruction, as of the passage of feculent matter through the intestine, the vascular communication is also intercepted and the circulation of blood arrested,—a condition which soon leads to gangrene.

The state of the hernial contents of the sac, in the early and advanced stages of strangulation; have been already sufficiently described, in speaking of the general structural changes of Hernia.

**Seat of Stricture.**—Generally, the stricture is situated at the *neck* of the sac; but it may be either in the neck, by thickening of this portion of peritoneum; or external to and around the neck, by constriction of the surrounding tendinous or ligamentous structures forming the hernial aperture. These structures do not exert any active pressure upon the neck; the protruded viscus passes through an aperture too narrow for its reception, and, pressing outwardly, is resisted by the unyielding boundaries of that aperture. Hence, the precise seat of stricture may be in any portion of its circumference,—at whatever part resistance is greatest. This structural condition will be noticed more particularly in connexion with special Herniæ. Occasionally, the stricture is situated in the *body* of the sac, which may have assumed an hourglass-shaped contraction. Lastly, sometimes it forms *within* the sac; as a band of adhesion, or there may be an aperture in the omentum constricting a portion of intestine.

**Symptoms.**—(1) *Local.*—The tumour is irreducible, and the impulse on coughing is diminished or altogether absent, owing to the stricture preventing a transmission of the shock to the contents of the sac. The situation of stricture may sometimes be thus determined, as Luke pointed out, by observing the line where the impulse ceases to be felt. There is some enlargement of the hernial tumour, if a pre-existing one; or it may have recently made its appearance. It is tense and elastic, the more so if intestinal, and in proportion to the accumulation of serous fluid in the sac; but if omental, the tumour may still retain its characteristic doughy consistence. Tenderness soon supervenes about the neck of the tumour, and is thence diffused over the abdomen, which becomes painful and tympanitic as peritonitis is established. The pain varies in kind and degree. Usually, referred more particularly to the umbilicus, there is a peculiar sensation of constriction across the belly, and perhaps a dragging-down sensation; or pain may be slight, or absent throughout. A constricted portion of *intestine* is functionally paralysed, so that its peristaltic action is arrested. The fæces and flatus accumulate in the intestinal canal above the seat of stricture, and complete constipation ensues; although the bowel below may perhaps act once, and thus somewhat relieve the sense of colicky distension. Vomiting soon sets in; first, emptying the contents of the stomach, then throwing up bile and mucus, and lastly, the contents of the intestine,—the vomited matters acquiring a more or less decidedly feculent character. *Omental* hernia is attended with similar symptoms, excepting that they are less severe, and the constipation is necessarily far less marked. The symptoms of strangulation are more acute if the hernia be recent and small, than if it be old-standing and large. Lastly, the position and respiration of the patient, as influenced by *peritonitis*, are peculiar. He

lies upon his back with the knees drawn up to relax the abdominal muscles, and the breathing is chiefly thoracic, in short hurried, catches, interrupted perhaps by hiccup,—always an unfavourable omen. (2) *Constitutional Symptoms*.—Inflammatory fever accompanies the development of peritonitis, and is denoted by the usual symptoms,—of a *sthenic* type in the young and vigorous, *asthenic* in the old and enfeebled. But the phenomena of the vascular and nervous systems are characteristic. The pulse is quick, small, and hard or wiry, and prostration speedily supervenes; the pulse increasing rapidly in frequency to 100, 120 or more beats per minute, and becoming proportionately weak and irregular, as collapse ensues. A cold, clammy sweat bathes the skin, and the expression of countenance is nipped and anxious; but there is often a notable relief of all the abdominal symptoms; the pain ceasing, the vomiting subsiding, perhaps even the bowels being relieved by an evacuation. Yet, in this deceitful state of tranquillity, the patient lies on the verge of death. Sometimes with *rupture* of a sphacelated portion of intestine, fæcal extravasation takes place, when an accession of sudden and most intense pain betokens that event; otherwise the *relaxation* coincident with sphacelus is a fatal omen, and in a state of overwhelming collapse, death occurs almost imperceptibly.

**DIAGNOSIS.**—To determine the diagnosis of strangulated Hernia, a *tumour* of hernial character, must always be sought for and discovered. But the size of such tumour is unimportant—a small hernial protrusion embracing only a portion of the circumference of the intestine, will be quite sufficient to produce the most severe constitutional symptoms of Hernia. A patient may have suffered for some days from nausea and vomiting, with frequent desire to relieve the bowels, and inability to evacuate, passing only perhaps a little wind. The co-existence of a hernial tumour with these symptoms will complete the diagnosis. Without such tumour, similar symptoms may depend on mechanical obstruction of the intestine within the abdomen, and as arising from various causes;—the pressure of a tumour, the ligature of a fibrous band, ileus, enteritis, or simply constipation. There are also the rare forms of internal abdominal hernia to be considered, in the absence of a tumour. A strangulated hernia being present, there may be a notable *absence* of the symptoms of strangulation,—local and constitutional. Thus, the usual tension of the tumour and tenderness about its neck, may be wanting, and there may be no abdominal pain or tenderness on pressure,—even with pus-forming peritonitis; vomiting also may be absent throughout the whole course of strangulation; while the circulation and nervous system are, perhaps, singularly irresponsive to the local condition. Some sharpness of pulse and anxiety of countenance, are, however, generally indicative of strangulation; and at length the patient succumbs to prostration.

The diagnosis of strangulated hernia from incarcerated, and from simply irreducible hernia, has been noticed in the definition of these several conditions of Hernia. *Inflamed* irreducible hernia, most nearly resembles strangulation. Hernia in this state exhibits all the local signs, and excites the constitutional symptoms of inflammation. The combination of those indications which characterize the condition of strangulation, does not, however, exist.

*Peritonitis conjoined* with irreducible hernia renders the diagnosis equivocal. But, the peritoneal inflammation cannot be traced to the neck of the tumour as its origin and source, and it may be most intense at

some distance from the sac ; while the constipation and vomiting are not conspicuous symptoms.

In *double hernia*, both of which are irreducible, one may be strangulated, and the other not. Here the diagnosis must be determined by careful comparative observation ; as to the local conditions of the two tumours,—in point of elasticity and tenderness of the neck, and to connect the abdominal and constitutional symptoms with one rather than the other, as their source.

Other tumours, compared with strangulated hernia, must be distinguished by their respective characters.

*Causes.*—Sudden protrusion of a viscus, as of intestine or omentum, by some violent exertion, is the common cause of strangulation. But it occurs in two distinct conditions of hernia. In an *old standing* and perhaps irreducible hernia ; a larger descent than usual may take place, through an aperture too small, although previously large, and the hernial contents gradually undergo strangulation. In a *newly-formed* hernia ; the protrusion takes place through a tight and previously undilated aperture, and the hernial contents rapidly become strangulated. *Distension* of a pre-existing visceral protrusion, as of the intestine by fæces or flatus, and of the omentum by venous congestion ; may occasionally induce strangulation. Spasm, formerly regarded as a cause, can scarcely have any effect ; the hernial aperture being tendinous or ligamentous, or certainly not muscular, although indirectly subject to the action of the abdominal muscles. No *period of life* is exempt from the liability to strangulated hernia ; it occurs in the newly-born infant and in centenarians.

*Treatment.*—The indication is the removal of the constriction from the strangulated hernial tumour. This may be accomplished by gentle reduction of the hernial contents through the stricture ; or, failing thus to fulfil the indication, then an operative proceeding for the division of the stricture, must be had recourse to, without a moment's delay.

(1) *The Taxis.*—This term signifies the manipulative procedure of reducing a hernia ; it must be conducted on certain principles, and should be continued only for a certain time.

The principles are, to dilate the neck of the sac, and to diminish the bulk of the protrusion. In accordance with the former principle, the patient should be placed in the position requisite to relax any unfavourable muscular action on the neck of the tumour. The recumbent posture with the knees drawn up and the body inclining forwards, will relax the abdominal muscles. With this view also, the patient's attention may be diverted by asking him questions occasionally during the attempt at reduction. Steadying the neck of the tumour, as far as practicable, with one hand, the other should grasp the body of the tumour ; when by a gentle, uniform, compressive manipulation, the hernial contents may be returned. The direction of the pressure is specially important ; it should always be made in the course of the hernial descent. Slight traction downwards before using compression will sometimes facilitate reduction ; apparently by freeing the contents from the neck of the sac. The taxis having been thus employed for a few minutes, any fluid in the sac may partially pass into the abdomen, accompanied with some diminution in the size and tension of the tumour ; the flatus of the intestine may also escape into the intestinal canal above the stricture, accompanied with a gurgling sensation and sound, and then the intestine goes up with a sudden jerk. Omentum may then have to be reduced.

Dilatation of the hernial aperture, by insinuating the tip of the *finger* into it, is a manœuvre which has been successfully resorted to by Baron Sentin; and this procedure seems to have been employed effectually, in some cases, by Mr. Erichsen. It is most practicable in femoral hernia,—where the upper edge of the saphenous opening is sharply defined, and especially as felt in a thin person; and when the stricture is seated at the external abdominal ring.

The *amount* of compression justifiable, varies with the state of the strangulated intestine, as denoted by the one symptom—vomiting. Before this has occurred, the pressure should be gentle; after vomiting, any manipulation must be particularly delicate and cautious, lest the gangrenous bowel be irreparably damaged or burst. The *duration* of the taxis is equally important; for moderate but continued manipulation may be as damaging as a violent effort at reduction, and any such handling is more likely to induce inflammation. Half an hour may be roundly stated as the period beyond which the taxis should not be prolonged.

*Further Measures for Relaxation.*—If the taxis do not soon succeed, certain auxiliary measures may be resorted to with advantage; and, under such influences, reduction should be re-attempted. The patient may be placed in a hot bath (96°—100° F.), and allowed to remain until some faintness supervenes, during which period, the taxis is reapplied in the bath. This failing, he should be removed, and wrapped in blankets. Then chloroform may be administered cautiously, and under its influence another attempt at reduction be made, yet once more only.

It would be idle to even enumerate all the other measures which have been resorted to; some are pernicious, all are useless, with perhaps two exceptions. *Opium* may be administered with advantage in one period of strangulated hernia. When vomiting has commenced, and the stomach has been emptied by two or three vomits, there is—according to Mr. Birkett's careful observation—a short interval of repose which continues until regurgitation takes place from the small intestines. If this moment be seized, and a full dose of opium in solution, with a little stimulus, be given, the hernia can sometimes be reduced. But when once the vomiting of regurgitated fluids has supervened, the inward administration of medicine is pernicious. Purgatives are positively killing, and enemata at least useless. Yet how often do we hear of or meet with patients who have been positively drenched with such medicines for days or even a whole week, under the care of a chemist or possibly under medical supervision, before an operation for the relief of strangulation. This sad mistake occurs commonly by overlooking the nature of the symptoms; the constipation and vomiting being regarded simply as a disorder of the stomach and bowels, without making any examination to discover a hernial tumour. Sometimes the essential pathology of strangulated hernia seems to have been misunderstood, as in a case alluded to by Mr. Birkett; an operation having been urged for the relief of a strangulated hernia, the gentleman in attendance immediately replied:—"But will it not be desirable to wait until the vomiting has ceased before the performance of the operation?" *Cold applications* to the tumour, by means of the ice-bag or freezing mixture, seem to have some advantage in facilitating reduction by the taxis. The blood-vessels being thus partially emptied, the bulk of the protrusion is somewhat diminished. But the tendency to gangrene will be increased by prolonged cold. Such applica-

tions are more useful as preventive of strangulation; and after strangulation has existed twenty-four hours, cold is inadmissible.

*Injuries inflicted in the employment of the Taxis.*—They affect separately, or in combination,—the hernial contents, the sac, the integumental coverings. The nature of the injury is always the same—contusion or bruising, and the bowel may be lacerated or burst.

Thus, with regard to the *hernial contents*; intestine being most delicate, is more commonly injured than omentum. Indeed, the latter may sometimes protect the former. The injury liable to be done to the bowel should be estimated less by the symptoms of strangulation than by the violence and prolongation of the attempts employed in the taxis. After the first act of vomiting, and during the succeeding twenty-four hours, the bowel may be killed by manual pressure, or cut by pressure against the hernial aperture. In either case, the entire calibre of the bowel becomes divided; forming an artificial anus, or death takes place in consequence of feculent extravasation backwards into the abdomen. After the expiration of twenty-four hours, the softened state of the bowel will probably cause it to yield under any violent or prolonged use of the taxis. Rupture usually occurs at the convex border of the gut, at the furthest point from the mesentery, and the rent is in the direction of the circular muscular fibres.

The *signs* of burst bowel are very characteristic. If an enterocele, the bowel glides away from the pressure of the finger and the tumour disappears. But this apparent reduction is not accompanied with that sudden and peculiar gurgling subsidence which the return of an unburst bowel into the abdomen produces. The patient immediately complains of intense pain in the abdomen, vomiting ceases, succeeded however by retching and hiccup with utter collapse and death. Sometimes, inflammation and suppuration take place in the sac, and extending through its coverings, the abscess bursts, leaving a fistulous communication with the interior of the intestine. Violent compression also produces hæmorrhage into the sac, forming a mixture of blood and coagula with the serum; or by aggravating the inflammation, flakes of lymph or puriform effusion result.

The hernial *sac* is liable to two forms of injury; displacement, and laceration or rupture. Both may happen together, and almost necessarily in connexion with considerable force.

By *displacement*, the sac is detached, to a greater or less extent, from the surrounding textures. This injury occurs usually in inguinal hernia. The neck of the sac is more frequently affected than any other portion. It becomes detached from the inner surface of the internal abdominal fasciæ, and carrying with it the surrounding portion of parietal peritoneum, a pouch is thus formed within the fascial membrane of the abdomen; into which the hernia may be forced, and being retained therein, is lost to touch and sight. Sir Charles Bell recorded a case of this injury, in the London Medical Gazette, 1828. The entire hernial tumour may be pushed into the abdomen, in a mass; the tumour disappearing, whilst the contents are still strangulated by the mouth of the sac. This injury—first described by French writers, as “*réduction en bloc*,” is of rare occurrence. Mr. Luke’s paper in the Med. Chir. Trans., 1843, will give further information.

By *laceration* of the sac, commonly its neck along the posterior aspect, the hernial contents escape through the rent into the sub-peritoneal con-

nective tissue. Extending backwards under continued pressure, and detaching the neighbouring peritoneum, the hernia is lodged between that membrane and the internal abdominal fascia. This injury is more frequently produced in that variety of inguinal hernia, known as congenital, or its sub-form, infantile hernia. It is inflicted very easily under the influence of chloroform, and especially in a youthful patient.

The *signs* are these:—the tumour becomes smaller and flaccid, slowly diminishing as the pressure is continued until it almost disappears; but as the hernial contents escape, the Surgeon fails to feel the well-known sensation of a gurgling jerk produced by the return of bowel into the abdomen, and the direction of this apparent reduction seems wrong. Symptoms of strangulation recur and perhaps with aggravated severity, the tumour also may reappear and recede again under the application of slight pressure.

The *coverings* of the hernial sac are liable to injury from rough handling; contusion producing ecchymosis of the integument, subcutaneous extravasation of blood and œdematous infiltration, and inflammation, leading to suppuration and sloughing.

*Symptoms after Reduction.*—Vomiting ceases usually, or it may continue for a while as the effect of chloroform. The pain in the abdomen and sense of constriction, are immediately relieved, and soon cease.

*Persistence of the symptoms of Strangulation*, after *apparent* reduction, may arise from three conditions of injury; rupture of the intestine with feculent extravasation into the abdomen; displacement of the sac into the abdomen, or apparent reduction en bloc; rupture of the sac, and apparent return of its contents. These conditions—thus agreeing in the disappearance of the tumour—may perhaps be diagnosed by their structural modes of production, already noticed. Certain conditions of the hernia itself, after *real* reduction, may also perpetuate the symptoms; such as internal stricture—within the sac, reduction having overcome only the external stricture of the hernial aperture; or persistent constriction of the viscus which had been protruded, as the result of plastic effusion forming a peritoneal band. The still strangulated viscus remains functionally paralysed,—the bowel not regaining its peristaltic action, and the constricted portion becomes gangrenous; with unabated continuance of peritonitis, constipation and vomiting as the symptoms of strangulation.

The *treatment* of these various misadventures of the taxis may be conducted on one and the same general principle. With *persistent* symptoms of *strangulation*, after apparent or after real reduction; an operation must be resorted to, with the view of reaching the still existing seat of stricture and dividing it. Care must be observed to modify the operative procedure according to the structural conditions of the hernia, as already described; especially in regard to the apparent reduction arising, either from displacement of the sac into the abdomen, or from rupture of the sac externally. With a constricted portion of bowel after its reduction, of course no stricture would be discovered by operation.

Any temporary continuance of the symptoms of strangulation, due to previous constriction, must not be mistaken for persistence, due only to a persistent cause. Their gradual subsidence or continuance, the case being watched from hour to hour, will probably enable the Surgeon to determine as to the necessity for operative interference.

(2) *Operation for Strangulated Hernia.*—Herniotomy.—The Taxis

having failed to effect reduction; an operation for the removal of the impediment to reduction,—by division of the stricture and liberation of the protruded viscus, should be resorted to without a moment's delay. The general indication as to the *absolute necessity* and *extreme urgency* of this operation may be thus stated:—persistent vomiting, and especially of a feculent character, showing the regurgitation of the contents of the small intestine.

The taxis must be forthwith abandoned; or, if not previously tried, it should be gently tried only once under the immediate administration of chloroform; and that attempt failing, any further delay of operation would be attended with hourly increasing peril. According to the results of Mr. Luke's experience, of 69 cases of strangulated hernia operated on within the first forty-eight hours of strangulation, 12 died, or 1 in 5·7; whereas of only 38 cases operated on after more than that period had elapsed, 15 died, or 1 in 2·5,—showing a fast increasing proportion. This large mortality is due, not to the operation, in itself, but to the state of the hernial contents when operated on. Gangrene will have almost inevitably supervened, and aggravated probably by repeated attempts at manipulative reduction. Two maxims, by Surgeons of large experience, may serve to impress on the mind the danger of prolonged taxis, and of the delay of operation. Desault observed,—“Always think favourably of a case of strangulated hernia when the taxis has not been used;” and Mr. Hey observed, that—“I have often regretted performing the operation too late, but never having done it too early.” Whenever, therefore, the taxis has failed, and perhaps vomiting is persistent, the operation must be resorted to at once, under the influence of chloroform,—which will have been already administered in the case of a first and only attempt to accomplish reduction by taxis at the extreme period of urgency.

*Modes of operation.*—Two modes of performing the operation are generally applicable; either by opening the hernial sac, exposing its contents, and dividing the stricture wherever situated, *within* the sac; or by dividing the stricture *outside*, leaving the sac unopened,—as was originally performed by Petit in 1718, and revived by Aston Key and Luke. Of the two latter authorities; the one wrote an admirable memoir On the Advantages and Practicability of Dividing the Stricture in Strangulated Hernia on the Outside of the Sac; the valuable paper of the other appeared in the Med.-Chir. Trans., vol. xxxi. M. Guérin has divided the stricture subcutaneously, as described in the Gaz. Méd. de Paris, Aug. 1841.

*Conditions for choice of either Operation.*—That of not opening the sac, is always preferable from its comparative safety and simplicity; whenever it may be effectual for the relief of strangulation and reduction of the hernia. The guiding principle of choice may perhaps be thus enunciated:—whenever the symptoms are of such moderate severity that the hernial contents might be safely returned by taxis,—were it practicable—any existing stricture outside the sac may be divided and the hernia reduced; on the contrary, whenever the symptoms are of such severity as would indicate a state of the bowel, especially, which would be hazardous to attempt to reduce by taxis, the sac must then be opened. Hence, Mr. Birkett would define the following to be the principal conditions that should determine this election;—for not opening the sac,—that the symptoms of strangulation have existed only a few hours and have not been very severe, the vomiting not stercoraceous nor prostration extreme,

the hernia a simple enterocele, and which has not been subjected to forcible attempts at reduction; for opening the sac,—prolonged strangulation, stercoraceous vomiting and marked prostration, the hernia compound,—an entero-epiplocele, and which has been subjected to repeated, protracted, or forcible taxis. Duly comparing these opposite conditions of operation; it will appear that the number of cases of strangulated hernia eligible for operation, without opening the sac, is unfortunately very limited.

The *relative results* of both modes of operation may be gathered sufficiently from the following statistics. Out of 84 cases of hernia operated on by Mr. Luke; in 25 the sac was opened and 8 died, whereas in 59 the sac was not opened and only 7 died. The additional cases reported by Mr. N. Ward, give a total of 36 deaths in 153 cases of Petit's operation. On the other hand, of 77 cases reported by Sir A. Cooper, in which the sac was opened, 36 proved fatal; and of 545 cases collected by Dr. Turner, 260 died. Regarding *femoral* hernia in particular, where the stricture is commonly outside the sac; of 31 cases operated on by Luke, in 7 only was it necessary to open the sac. Inguinal hernia cannot generally be relieved externally; of 20 cases operated on by the same Surgeon, in 13 it was necessary to open the sac.

(a) *Operation in which the sac is opened.*—The *instruments* required are few and simple—a scalpel with a single-cutting edge, dissecting forceps, directors, straight and curved; Key's broad hernia-director, bistouries blunt-pointed, straight and curved for dividing the stricture, or Sir A. Cooper's hernia-knife; retractors. It will thus be seen that the only peculiar instruments, are the hernia-director and the hernia-knife.

The *operation* consists, in exposing and opening the sac, finding and dividing the stricture, the management of adhesions and the visceral protrusion. The patient lying down on the edge of the bed or table, with the part well exposed; the bladder is emptied and the hair shaved from the seat of operation, in the ordinary inguinal and femoral herniæ. An incision is then made of sufficient length over the neck of the tumour, by pinching up a fold of integument, and transfixing with a scalpel through its base; the back of the knife being turned towards the hernia, the edge is made to cut outwards through the fold of skin. On letting go the fold a linear incision is presented in the direction of the neck of the tumour, which may be extended at either end as occasion requires. The cellular texture and fat are then carefully divided, on a director or by a scratching dissection, with the scalpel and forceps; this precaution will be necessary, as the integumental incision may have almost exposed the sac, so little is there seen of the separate layers or coverings of hernia as distinguished in the diagrammatic descriptions given in anatomical works. An anatomical or an inexperienced operator may make as many layers of covering as he pleases; and with no harm to the operation, but perhaps with safety to the patient. Any small bleeding artery had better be secured by a twist with the forceps, lest it should obscure a clear view of the sac. This may be recognised by its tension and whitish appearance; thin and translucent, and often coloured from the hernial contents, in recent hernia; thick and opaque-white, and not transmitting any colour, in old hernia. *To open the sac*; a little bit should be pinched up with the forceps, and by a slight rotation having ascertained that no portion of intestine is included, the knife is laid flat and a small button-hole aperture made under the point of the forceps; a little serous fluid will escape, having a yellowish

or brownish colour according to the state of the hernia, and a small bleb of glistening intestine or a bit of granular fatty omentum, more or less darkened in colour, may rise up through the aperture in the sac. A director is introduced and care taken that it lies entirely between the gut and the sac, no portion of bowel overlapping. This can perhaps be plainly seen through the more translucent peritoneal sac of a recent hernia; but with an opaque sac, it will be advisable to use the broad director as a safeguard. Then, introducing a probe-pointed bistoury, along the groove of the director, the sac is slit up towards its neck—the usual seat of stricture; and turning round the instrument, a slit is made towards the fundus, so as to thoroughly expose the hernial contents. A practised operator will perhaps prefer the finger to a broad director, and I almost habitually use it as such instead.

The *seat of stricture* is sought for by gently examining the visceral contents of the sac. Situated commonly at the neck of the sac, the protrusion is there constricted and pedunculated. The stricture will, therefore, not generally be visible, but it can be easily felt. Before passing the finger up to the neck of the sack; the body of the hernia, including both the sac and its visceral contents, should be gently steadied with the other hand, in order not to drive the neck before the finger. At the same time, the finger is passed up and its point slightly insinuated, as a protector, between the protrusion and the stricture. Then, using the finger as a director, the blunt-pointed hernia-knife is slipped up along the curve of its palmar surface, and just sufficiently far to bring the cutting-edge of the knife under the stricture. On gently elevating the handle, the stricture yields with a creaking sound; but it should be divided to a very limited extent, from one-eighth to a quarter of an inch, or just sufficient to admit the point of the finger to pass on into the abdomen when the knife is withdrawn. The *direction* in which the stricture should be divided varies with the hernia, and will be particularly noticed in describing the operation as performed for inguinal and femoral herniæ.

*Reduction* of the visceral protrusion is determined by the state of the parts. They should be carefully examined to discover; whether there are any adhesions either between the parts, or between them and the sac; and to ascertain also whether the protruded parts are in a sufficiently healthy state for reduction.

If the hernia be, as usual, an entero-epiplocele; the intestine will probably be seen, or more entirely, on drawing aside the omentum. Then—if both be healthy and without adhesions—the intestine should be returned first, by a gentle kneading action with the fingers to empty the gut and replace it, followed by a similar manipulation to replace the omentum. In concluding the operation, the point of the finger should be gently introduced into the abdomen to feel that the mouth of the sac is free; excepting in those unusual cases, where the bowel or omentum is allowed to remain unreduced. The *bulk* of intestine, owing to its quantity and distension with flatus, will sometimes render the reduction of the whole mass impracticable. In one such case, Mr. Tatum punctured the bowel with a grooved needle, and allowed the flatus to escape. The result was completely successful, but the justifiability of this instance as a precedent may well be questioned.

*Adhesions* must be dealt with according to their nature and connexion with the bowel or omentum. As to the *bowel*; recent adhesions may be gently separated, between a coil of bowel, or between it and the sac; *old*

adhesions may be divided, when thread-like, but when extensive their division would run the risk of injuring the bowel. *Omental* adhesions may be divided a little more freely, or a small portion of omentum may even be left adherent to the neck of the sac.

With a *gangrenous state* of the intestine and omentum; the state of the *bowel* will determine the propriety of its reduction, or of the formation of an artificial anus. Gangrene short of sphacelus is not irrecoverable, and this more favourable condition is indicated by the bowel, however approaching to black, still retaining its peritoneal lustre. In this state, the bowel may be returned just into the abdomen; where it will perhaps recover itself; or in the event of sloughing, the aperture may be closed by peritoneal adhesion, and the slough pass into the intestinal canal without fecal extravasation; or the feces and slough will escape through the wound, as the most unfavourable issue. Mr. Aston Key advocated this procedure. *Sphacelus* is of course irrecoverable, and the only difference of opinion is as to the propriety of dividing the stricture. Division has been said to be unnecessary or even injurious, and such was the opinion of Travers and Lawrence; on the other hand, division of the stricture was advocated by Dupuytren, Sir A. Cooper, and Key; but also that the bowel should not be returned, and a free incision made into it to allow the discharge of feces through the wound. If the gut has already broken, a similar proceeding will be appropriate; division of the stricture, and the bowel left unreduced in the sac. In both these states of sphacelus, adhesions, consequent on peritonitis, form around the stricture at the neck of the sac; and thus retaining the bowel in position and preventing feculent extravasation backwards into the peritoneal cavity, an artificial anus becomes established.

The state of the *omentum*, and the quantity of it protruded; will determine with regard to this structure the propriety of its reduction, or of leaving it in the sac, or removing it. Gangrenous omentum should certainly not be returned into the abdomen; and inflamed omentum with extensive adhesions is equally unfit for reduction. But a large mass of protruded omentum, or an omental protrusion which has become hypertrophied, indurated, or otherwise changed in structure, as in old herniæ; are conditions which, if returned, would excite peritonitis. The omentum must either be left in the sac, or removed. If left in the sac, the advantage and disadvantage are these. Usually, the omentum shrinks up, and eventually the wound heals, but with more or less of a tumour remaining at the hernial aperture; a condition which may prove useful in plugging up the aperture, although it will interfere with the efficient application of the pad of a truss. Or, the omentum is liable to become inflamed, to suppurate and slough; delaying considerably the healing of the wound. Removal of the omentum therefore seems a justifiable resource, as compared with the results of leaving it. *Ligature* of the mass is always necessary; both to prevent the risk of hæmorrhage from the highly vascular omentum, and the peril of extravasation backward into the peritoneal cavity, beyond the reach of surgical interference and which would be provocative of peritonitis. The mass may be ligatured by means of a single ligature of whipcord, tied tightly round the neck; or the omentum may be ligatured in successive portions, so as to tie the vessels separately. The one proceeding was formerly supposed to have the disadvantage of inducing peritonitis by contraction of the omentum; an evil consequence which has, however, been disproved by the results of

more recent experience, particularly in the practice of Mr. Pollock, Mr. Erichsen, and Mr. Holmes. Of 20 cases of hernia, at St. George's Hospital, in which the omentum was securely tied, a few died; but post-mortem examination showed the cause of death to have been, in all cases, independent of the ligature. But, ligature of the vessels singly has the advantage of more surely preventing hæmorrhage, when the ligatures become detached. In my own practice, I distinctly lost a patient owing to the uncontrollable hæmorrhage arising from the separation of a single ligature around the omentum *en masse*. Ligatured omentum may be *left* in the sac, or removed by *excision*. Of 11 cases, at St. George's Hospital, in which the omentum was allowed to remain, many recovered, although abscess and sloughing of its tissue occurred in some of them. Excision should be performed close to the external aperture; care being taken to leave the stump of omentum in the aperture, and to secure it there by fixing the ligature cords with a strip of plaster on the adjoining part of the abdomen. The stump thus occupying the orifice, is free in the event of hæmorrhage, and it forms a plug which permanently obstructs the descent of a hernia, and which is quite as effectual as when the whole mass is left. Ligature and excision of the omentum must always be very carefully performed; before applying the ligature, the omentum should be unfolded to see that it does not envelope a knuckle of intestine, and in using the knife, care must be taken not to touch the bowel.

The formation of a regular "omental sac" around the intestine, is described by Mr. Prescott Hewett, in the Med.-Chir. Trans. of 1844, and in the Path. Trans., vol. iii.

*Cysts* containing serous fluid or blood, are occasionally met with in the omentum; they resemble a knuckle of intestine. Their nature having been ascertained, the fluid may be discharged by puncture. The omentum is then managed according to the rules already laid down.

*Accidents in the Operation.*—*Wound of the intestine* happens occasionally; this accident occurred in the skilled hands of Sir A. Cooper, and in those of Sir W. Lawrence, Mr. Liston, Cloquet, and Jobert. It is liable to happen in either stage of the operation; in opening the sac, or in dividing the stricture. The one occasion of accident may generally be avoided by observing the precautions enjoined, in opening the sac; and the other by equally protecting the gut, in dividing the stricture. The escape of flatus and fæces will at once declare the nature of the accident; although of course the same discharge occurs when the gut yields by laceration from handling it in a softened and gangrenous state.

The *treatment* of wounded intestine is simple. A puncture may be secured by seizing the point with forceps, and casting a fine silk ligature around it, the ends of which should be clipped off close. An incision may be closed by the Glover's stitch. In either case, the bowel is then to be returned just inside the mouth of the sac. The case proceeds the same as in a wound of the abdominal parietes involving the intestine; and the result is not unfrequently successful, or the bowel giving way, an artificial anus forms.

*Wound of an artery.*—In dividing the stricture, an artery may be wounded; either as a sheer accident, owing to some anomalous course of the vessel; or from dividing the stricture in a wrong direction. The accident is more liable to happen to the deep epigastric or the obturator arteries, in the operations for inguinal and femoral herniæ.

*Treatment* consists in at once cutting down upon and securing the

bleeding vessel; an injunction easier given than carried out. As a precaution against such an accident under any uncertain circumstances, Mr. Erichsen recommends that the edge of the hernia-knife should be blunted by drawing it over the back of a scalpel; when it will still be keen enough to relieve the strangulation, whilst it will push before it any artery that may happen to lie in the way.

*Sloughing of the sac* rarely ensues after operation; it commonly terminates fatally, occasionally in recovery.

(b) *Operation without opening the sac*.—This modification of the operation for strangulated hernia is performed in precisely the same manner, short of opening the sac. The circumstances under which this limited operation would be advisable, have been already enumerated. The stricture is divided externally, by means of a probe-pointed bistoury; and the contents of the sac reduced by compression. In fact, the taxis is reapplied to the sac, now that the stricture is divided. That failing, there is no alternative but to open the sac, and complete the operation in the usual manner.

*Either modification* of the operation (*a* or *b*) for strangulated hernia is concluded, by bringing the line of incision in the integument together by two or three points of suture and strips of plaster; over which a pad-compress of lint should be applied, secured by a bandage, to prevent any re-descent of the hernia. It is well, however, to leave the lower angle of the wound open, to allow of the escape of bloody-serous fluid. When the sac is left occupied, and it is sought to establish an artificial anus, or such an opening has formed; the wound must be allowed to remain open.

*Treatment after operation*.—The general indications are; to restore the healthy state of the intestine and omentum, and to prevent or manage inflammation supervening as peritonitis,—and as complicated with a penetrating wound of the abdomen and a reduced state of the constitutional powers, in consequence of continual vomiting, starvation, suffering and alarm.

Two principles of treatment have been adduced, of opposite character; and both having been advocated by Surgeons of the highest eminence, they each demand notice.

In the one class are those Surgeons who administer purgatives almost immediately after the operation, and persist in their continuance “until the intestinal canal is completely unloaded.” Calomel, castor oil, extract of colocynth, and sulphate of magnesia, are administered by the mouth, and enemata per rectum.

Another—and as I think, a far more judicious class of practitioners, relying on the restorative power of nature,—the strangulation having been relieved—have but little recourse to medicine. Care is taken to leave the intestine at rest for some days to recover itself, and that the diet be light and unirritating, in the shape of farinaceous food and milk; while opium is had recourse to as occasion may require. Accordingly, this plan of treatment may be generally stated in the following order. The patient is placed on his back in bed, and not disturbed by talkative friends. Soon after the operation, a full dose of opium—thirty drops of the tincture, will be advisable. At this period, brandy-and-water may be given with advantage, in small quantities at intervals, as a stimulant; to recover the circulation from the state of prostration or collapse previous to the operation, and the effect of chloroform. The *bowels* will probably be

relieved naturally within the first twenty-four hours. But if not, they may be allowed to remain inactive for three or four days, when a mild enema of gruel and castor oil or salt and water, will be sufficiently laxative. Great distension and discomfort may justify relief at an earlier period; but cases not unfrequently proceed even to the healing of the wound without any intestinal action, and no evil consequence from the constipation. The diet, light and unirritating, must be given in small quantities at short intervals; the object being, the support necessary for reparation without loading the intestine. Thirst, often a distressing symptom, will be greatly allayed by sucking pieces of ice in the mouth.

*Peritonitis* supervening, is denoted by the usual symptoms of pain in the neck of the sac, spreading over the abdomen; this must be met by leeches, warm fomentations, and the ordinary treatment of peritoneal inflammation; in its acute and sthenic, or its chronic and asthenic forms. This plan of treatment must, therefore, be modified according to the opposite conditions of youth and age, strength and decrepitude, temperance and intemperance, and the peculiarities of health and disease.

The *wound* may heal partially or entirely by primary adhesion. But if inflammation and suppuration ensue, the sutures should be withdrawn, here or there, to allow of the free escape of discharge. Healing then takes place by granulation and cicatrization. When the patient gets up, he should wear a truss for some time, to support the part as yet in a weakened state. It may be disused, when there is no tendency to protrusion on coughing or other exertion.

The *prognosis* of strangulated hernia, in regard to the *mortality* after operation, will be determined; partly by the relative statistical results of operation with reference to the sac, as already shown; but partly and principally by consideration of the previous duration of strangulation, and the taxis to which the tumour has been subjected. The influence of strangulation has been shown by Luke's statistics, as to the results of operation for Strangulated Hernia.

Of 20 fatal cases operated on by Mr. Birkett in Guy's Hospital, the *periods of survival* were as follow:—

1	survived only 17 hours.
5	„ 24 hours, and less than 48 hours
4	„ 48 „ „ „ 72 „
1	„ 72 „ „ „ 96 „
1	„ 96 „ „ „ 120 „
3	„ 144 „ „ „ 168 „
1	„ 168 „ „ „ 192 „

3 survived longer periods, but with artificial anus.

1 died of bronchitis.

The causes of death were:—

Artificial anus, &c. . . . .	3	Perforation of bowel . . .	1
Prostration . . . . .	5	Bronchitis and cachexia . .	2
Acute peritonitis . . . . .	8	Neglect to seek surgical aid	1

Two-thirds, at least, of these patients lost their lives by the previous delay of operation for the liberation of the bowel; although this was done as soon as possible after admission to Hospital.

**ARTIFICIAL ANUS.**—This condition is said to exist whenever an aperture forms, or is made, in the intestine, through which its contents escape externally. The state of the bowel is, usually, gangrenous; whereby it

may have yielded in the sac before operation, or afterwards although returned into the abdomen; or it may be purposely laid open in the operation, to allow of the escape of fæces when that issue is inevitable. A healthy portion of intestine may, however, be accidentally wounded, in the course of operation, or by a penetrating wound of the abdomen. Artificial anus occurs most frequently in the inguinal, scrotal, and femoral regions; and in connexion with the small intestine. The kind of discharge will depend on the part of the gut opened, and its quantity on the size of the aperture. Whatever discharge there be, it is involuntary, and usually continuous.

Artificial anus differs according to the *extent* of aperture; as a sloughing perforation in the bowel, or sloughing of the entire circumference of the canal. Sloughing perforation usually occurs about the centre of the convex free-border of the knuckle of intestine,—at a point most distant from the mouth of the sac; a small ulcerated opening is produced, which does not interfere with the continuity of the intestinal canal, although allowing a portion of its contents to escape. This condition is sometimes distinguished as *fecal fistula*. Sloughing of the entire circumference of the intestine usually occurs at the mouth of the sac; the continuity of the canal is destroyed, and all the feculent matter escapes through the opening. The coats of the bowel are endowed with different powers of resistance to the process of ulceration whereby the slough is detached. Thus, by constriction of the bowel, a sulcus or groove is produced on its serous surface, without any trace of abrasion; but the mucous membrane presents a circular line of ulceration. This is sometimes limited to the upper and distended end of the intestine; the lower end, corresponding to the stricture, being unaffected. This difference may be owing to pressure of the distended bowel, and it occurs particularly where the knuckle of intestine lies in close relation with Gimbernat's ligament. Very rarely, as the result of long-continued constriction, and the pressure upon two portions of intestine laterally, their walls become adherent; ulceration takes place, and the continuity of the canal is thus naturally restored within the abdomen. An illustrative case is recorded in the Trans. Path. Soc., vol. x.

Intermediate conditions, between these two extremes, are met with; in which more or less of the circumference of the tube is destroyed, and a corresponding opening produced.

In the first condition referred to, repair frequently takes place; the hole closes, the integument heals, and complete recovery ensues.

In the second condition frequently, an artificial anus is at length established; and which never, or very rarely, undergoes spontaneous cure. Its completion is as follows:—The margin of the intestinal aperture—whether the whole or a portion only of the calibre of the intestine—becomes firmly adherent to the abdominal peritoneum; the openings of the upper and lower end of the canal are, at first, equal in size and lie almost in a continuous line. Subsequently, they unite at a more or less acute angle, presenting an intermediate spur-like portion or partition, of double-walled gut, opposite the mesenteric attachment, and bisecting the aperture externally. Of these two openings thus leading into the canal; the distal one, gradually ceasing to transmit fæces, becomes smaller; whilst the cardiac end, doing double duty, becomes dilated. The partition elongating, and acting as a valve, tends also to obstruct the intestinal passage of fæces; and thence the relative size of the two openings is still further exaggerated. Around the general aperture, the mucous mem-

brane sometimes acquires an everted, pouting appearance, or an actual prolapsus of the membrane may take place; while the surrounding skin usually is irritated and excoriated by the feculent matter escaping. The communication between the bowel and integument may not be *immediate*,—through the adhesive junction of the mucous membrane and skin; they may even be placed at some distance apart, a channel intervening between two apertures, internal and external. This modification of artificial anus occurs when the knuckle of intestine is lodged deeply; as in the neck of the sac, or within the abdominal cavity when an irrecoverable portion of intestine has been returned. In the latter case, fecal matter begins to issue, a few days after operation, and gradually increases in quantity; until, from merely staining the dressing, the nature of the communication is plainly declared.

*Treatment.*—This will depend on the size of the aperture. A *small* opening—a fecal fistula, may contract and close, by cleanliness and the pressure of a pad to restrain the discharge. This result may also be induced by the occasional introduction of a red-hot wire, or of the galvanic cautery. Closure can be directly effected sometimes by a plastic operation; by engrafting a small piece of skin over the aperture, or by making an oval incision on either side and bringing the outer edges of the incisions together by means of fine needles and twisted suture.

A *large* aperture, and fairly *established* artificial anus, will very rarely contract and close, but requires a special surgical operation to effect a cure. The object is twofold; to destroy or diminish the spur-like partition, in order to re-establish the continuity of the intestinal canal, and then to close the external aperture. The destructive part of this proceeding may, perhaps, be accomplished by repressing the septum, as Desault proposed, by means of a tent thrust into both intestinal openings. It can be more surely accomplished, and with equal safety provided due caution be observed, by strangling the septum; for which purpose Dupuytren's enterotome is admirably adapted. This instrument is simply a serrated forceps, worked by a screw across the end of its handle. The septum is grasped and compressed between the blades, and the pressure gradually increased by daily turning the screw, until the blades meet and the intervening septum has sloughed away. Plastic lymph is thrown out simultaneously, whereby the peritoneum should remain unopened, when the instrument is withdrawn. Hence the caution necessary, not to grasp the septum too high up towards the mesentery, and to regulate the compression in concert with the plastic effusion. The continuity of the canal having been re-established, the margin of the external anal aperture must be pared and brought together by hare-lip sutures.

A *permanent* artificial anus sometimes remains, having resisted all attempts at closure. This sad state may be made more tolerable by wearing a leathern receptacle or other contrivance; and it is gratifying to add, that patients have thus been enabled to live in comfort and the enjoyment of good general health for many years. An artificial anus situated high up in connexion with the intestine, and which discharges chyle or chyme, will of course constantly deprive the patient of nutriment; and this loss must be supplied by a proportionately increased quantity of nourishing food.

**DOUBLE HERNIA.**—A protrusion on both sides of the body, symmetrically, in the same parts, or unsymmetrically, in different regions, not unfrequently occurs. More than two such herniæ are occasionally met

with; and Sir A. Cooper records a case of six co-existing herniæ in the same person; three on one side, an inguinal oblique, a direct, and a femoral hernia, with the same on the other side. In any such case, symptoms of strangulation may be referable to this hernia or to that, and it is sometimes very difficult to determine which is the seat of strangulation. Hence, in double hernia, the operation may be performed on that side which when the sac is open presents no appearance of being strangulated. What should then be done? The Surgeon is justified in operating on the other side, with the view of saving the life of his patient. An illustrative case of double operation in double inguinal hernia, and a successful result, happened in the practice of Dupuytren; and it may be referred to as a precedent under similar circumstances. The case is related in the *Leçons Orales*, 1832, tome i. p. 583.

## CHAPTER LIII.

### SPECIAL HERNIÆ.

**INGUINAL HERNIA.**—*Structural conditions.*—Inguinal hernia is that form in which the visceral protrusion occupies part or the whole of the inguinal canal,—presenting an *incomplete* hernia or *bubonocoele*; or passing through the external abdominal ring, it becomes a *complete* or *scrotal* hernia, sometimes named *oscheocoele*. In the female, it passes into the labium. The hernia occurs in two principal varieties, as to its direction and relation to the deep (internal) epigastric artery; and which are designated accordingly, the *oblique* or *external* inguinal hernia, and the *direct* or *internal* inguinal hernia. Thus, in point of direction, the hernia may take place through the internal abdominal ring and follow the oblique course of the spermatic cord in the inguinal canal, thence perhaps passing through the external ring and into the scrotum; or, the protrusion may come directly through the conjoined tendon of the internal oblique and transversalis muscles, into the canal, just behind the external abdominal ring, thence perhaps passing through that ring into the scrotum. With relation to the epigastric artery; in the oblique variety, the mouth of the sac is external; in the direct variety, it is internal to that vessel. Oblique inguinal hernia is named *congenital*, when the visceral protrusion lies within the tunica vaginalis, as its sac, in contact with the testicle; and *infantile* hernia, when the protrusion carrying before it a peritoneal sac, lies just behind and dips into the tunica vaginalis as an independent sac—constituting what is also termed *encysted* hernia.

There are, then, three varieties of inguinal hernia; oblique or external, direct or internal; congenital, and its sub-variety, infantile or encysted.

**OBLIQUE INGUINAL HERNIA.**—*Course.*—This is the most common form of inguinal hernia. Its course is the same as that of the testicle in its passage from the internal abdominal ring through the inguinal canal and external ring into the scrotum; this route corresponding also to the spermatic cord in the same extent of its course.

*Anatomical coverings, and relations.*—The coverings of oblique inguinal hernia consist of those layers of different textures which successively invest the protrusion, in its formation and progress. They are the same investments that the spermatic cord receives,—seven in number, and they

may be conveniently enumerated from within, outwards, in the order of hernial development, as follow; peritoneal pouch forming the sac of the hernia, its sub-serous cellular tissue, and the fascia transversalis abdominis or infundibuliform fascia (Fig. 397); cremasteric fascia, consisting of

FIG. 397.\*

looped fibres of cremaster muscle proceeding from the internal oblique, with interstitial cellular texture; intercolumnar or spermatic fascia, consisting of tendinous semicircular fibres passing across between the pillars of the external abdominal ring, and thence prolonged downwards from the upper margin of the ring; superficial fascia, containing fat; and skin. These anatomical coverings are interesting with reference to the development of oblique inguinal hernia; but they become so altered in appearance and united by pressure, as to have much less importance surgically.

The relations of the inguinal canal, spermatic cord and testicle, to the visceral protrusion, and of the deep epigastric artery to the mouth of the sac, are specially important.

The *inguinal canal* is the interval between the abdominal parietes, just above the inner half of Poupart's ligament; it extends obliquely down-

\* *a*, external oblique muscle reflected. *bb*, internal oblique, arching over and covering the internal abdominal ring. *c*, transversalis muscle. *d*, conjoint tendon. *e*, rectus muscle, sheath opened. *f*, fascia transversalis. *g*, triangular aponeurosis of conjoint tendon. *h*, cremaster. *i*, infundibuliform fascia. (John Wood.)

wards and inwards, about one inch and a half in length, from the internal abdominal ring to the external abdominal ring at the crest of the pubes. Its boundaries, and thence the relations of inguinal hernia in the canal, are thus formed:—anteriorly by both abdominal oblique muscles over the outer half-inch of the canal, and the aponeurosis of the external oblique alone, the inner inch; posteriorly, by the fascia transversalis and the conjoined tendon of the internal oblique and transversalis muscles, the fascia extending along the outer half-inch of the canal, corresponding to the internal oblique, and the conjoined tendon, with the fascia transversalis behind it, along the inner inch, corresponding to the aponeurosis of the external oblique. Inferiorly, the floor of the canal is formed by the junction of the fascia transversalis with Poupart's ligament; and superiorly, it is limited only by the apposition of the muscles.

The *cord* lies behind or underneath the hernia, the *testis* below and somewhat behind its lowest part—the fundus, and these two are always distinctly separate. Occasionally, the elements of the cord are dispersed by the hernial descent; the vas deferens lying on one side and the spermatic vessels on the other; and rarely, the cord lies partially or entirely in front of the hernia, the testicle also below being in front. In the latter case sometimes, the elements of the cord are spread out in front of the hernia. The *epigastric artery*, arising from the external iliac about a quarter of an inch above Poupart's ligament, bends inwards and ascends beneath the fascia transversalis, immediately behind and *internal* to the mouth of the sac—at the internal abdominal ring, which is thus placed external. The course of this artery varies, however, with the duration of the hernia, and occasionally owing to an abnormal origin of the vessel. In old-standing hernia, the dragging pressure of the tumour downwards and inwards, curves the artery in that direction towards the outer edge of the rectus muscle; until it may thus be brought internal to the situation of a direct hernia. An *abnormal origin* of the artery occurs comparatively rarely; its position may be shifted upwards on the trunk of the external iliac, from the level of Poupart's ligament, as high as two inches and a half above it; or the vessel may arise from another source,—the obturator; or from below the ligament, being transferred to the superficial or the deep femoral artery.

Of these abnormal sources of the epigastric artery; the first has no relation to the internal abdominal ring; the two latter may have special relation to the crural ring, and therefore to femoral hernia.

*Seat of Stricture.*—Commonly, the stricture is situated at the mouth of the sac, in the internal abdominal ring; next in order of frequency at the border of the internal oblique muscle, in the inguinal canal; lastly, at the external abdominal ring.

**DIRECT INGUINAL HERNIA.**—*Course.*—This variety of inguinal hernia comes forward through a small triangular space, bounded by the epigastric artery *externally*, the margin of the rectus muscle on the inner side, and Poupart's ligament,—its inner portion, below. This space is situated, just behind the external abdominal ring, the conjoined tendon and fascia transversalis intervening.

*Anatomical Coverings, and relations.*—In number the coverings are the same as those of the oblique variety, and in kind they are the same, with one exception; the conjoined tendon is substituted for the cremasteric fascia. Thus, enumerating them in the order of hernial development, the coverings of direct inguinal hernia are; peritoneal pouch or sac, sub-serous

cellular tissue, fascia transversalis, conjoined tendon, sometimes ruptured, intercolumnar fascia, superficial fascia, skin. The *spermatic cord* lies on the outer side of the sac, the testicle below the fundus, and both are distinctly separate; the epigastric artery also courses up *external* to the mouth of the sac, curving over it inwards, so as sometimes to embrace the upper as well as the outer margin.

*Seat of Stricture.*—Commonly, the stricture is situated at the mouth of the sac; next in frequency at the conjoined tendon, when ruptured; lastly, at the external abdominal ring.

In the *female*, the anatomy of Inguinal hernia, oblique and direct, is essentially the same as in the male; except that the round ligament in the inguinal canal takes the place of the spermatic cord. Females are liable to both forms of inguinal hernia, the oblique occurring at very early periods of life. Excepting umbilical hernia, oblique-inguinal is the only kind developed before five years of age; and until the age of puberty, it is more common than any other variety of hernia. This form is not much more rarely met with than femoral, as generally supposed. Thus, in 1582 females, affected with hernia, in one form or the other, who came under Mr. Kingdon's observation; 761 had inguinal hernia, and 812 femoral hernia. Or, the one was only 30 less than half the total number, whilst the other was only 30 more than half that number.

*Signs of ordinary Inguinal Hernia.*—The *oblique* variety commences as a slight fullness or swelling at the internal abdominal ring, just above the centre of Poupart's ligament, next, passing downwards and inwards in the inguinal canal, it presents an oblong tumour having that direction, in this situation. (Fig. 338.) Still further protruding through the external

FIG. 338.

abdominal ring and descending into the scrotum, or the labium in the female, the tumour enlarges into a globular form on that side. It may attain an enormous size, extending down even to the knee, as in cases to which I have already referred; and a far smaller size in women. But—in males—the testicle can always be felt distinct, at the bottom and back part of the fundus. The usual symptoms of hernia are perceptible; enlargement and impulse on coughing in the erect attitude, diminution and disappearance of the tumour when compressed in the recumbent position. These symptoms are, however, more or less perceptible, according to the size of the hernial protrusion; being less so when it occupies the inguinal

canal, as *bubonocoele*, and most conspicuous in *scrotal* hernia. In old-standing oblique hernia, the neck of the sac is dragged downwards and increases towards the middle line; so that the distinctive shape of the inguinal portion is lost, and the tumour comes to resemble the next form of inguinal hernia.

*Direct* Inguinal hernia presents a tumour, which differs in situation, and somewhat in shape, and size, from that of the oblique hernia. This direct variety is situated at the external abdominal ring, near the root of the penis, the outer portion of the inguinal canal remaining unoccupied; the tumour is more globular, not pyriform as in the oblique, and it has a wider neck; usually, it is not so large. The other symptoms are similar.

Both varieties of inguinal hernia may co-exist in the same individual; or double inguinal hernia, one on either side, is occasionally met with. Not unfrequently, the hernia on one side is incomplete,—a *bubonocoele*, on the opposite side to an ordinary complete inguinal hernia,—a *scrotal* hernia.

CONGENITAL HERNIA.—This variety of oblique inguinal hernia was first noticed by Haller in 1749, and its nature was more particularly described by John Hunter and Percival Pott. The peculiar structural condition is this; the visceral protrusion lies in the tunica vaginalis, with, and in contact with, the testicle; when that organ has previously descended from the abdomen into the scrotum.

The course, coverings, and relations of the hernia are the same as those of the ordinary oblique; except that the *sac* is the tunica vaginalis, and the relation of the *testis* is immediate, it being within the sac, although the situation of that body below and somewhat behind the hernial contents—not the fundus of the sac—remains unaltered. The visceral protrusion passes down from the abdomen, through the vaginal process of peritoneum which connects the peritoneal cavity with the tunica vaginalis; this process having remained unobliterated after birth, instead of closing as usual in about three weeks or a month. Paletta states that, normally, the complete closure of the vaginal canal takes place from the twentieth to the thirtieth day after birth. But, when the canal remains pervious, although the tendency to this hernia thus dates from birth, it may not occur for years afterwards. Hence the hernia itself is not properly speaking congenital, and it might be more correctly designated, as Mr. Birkett has suggested, “hernia into the vaginal process of the peritoneum.” Occurring, therefore, in early life,—in infants a few weeks or months old; congenital hernia also occurs, for the first time, at perhaps any subsequent period of life. Instances between the ages of eighteen and twenty-five are related by Velpeau; and two by Erichsen, at twelve years old and thirty years of age. In both the latter cases Mr. Erichsen operated at the ages respectively of thirty-five, and fifty; and I once operated on a right congenital hernia in a middle-aged man, in whom after death, unfortunately, I found the left vaginal process completely pervious, admitting a large-sized elastic catheter from the internal abdominal ring to the testicle. Thus this was a case in the adult of strangulated congenital hernia on one side, and the persistent structural condition without hernia on the other side. The preparation is in the Museum of the Hospital.

The relation of the *testicle* to congenital hernia is very important; associated with congenital persistence of the vaginal process of perito-

neum, the testis on the same side frequently occupies an abnormal situation. There will then be two persistent congenital conditions, both arrests of development; the one, an unobliterated state of the vaginal process of peritoneum, which should be temporarily provided only as a sheath for the descent of the testicle into the scrotum; the other, an arrested descent of the testicle. Congenital hernia may, therefore, not as usual contain the testicle in the hernia vaginalis or hernial sac, the testis never having descended into the scrotum.

*Abnormal situations of an undescended testis*, and accompanying conditions of the vaginal process. These modifications are as follow:—

(1) *Testicle* within the abdomen; the vaginal process extending into the inguinal canal, but not reaching further than just through the external abdominal ring, or into the upper part of the scrotum. (2) Fixed in the inguinal canal out of the reach of manipulation; whilst the serous canal, passing into the scrotum, forms a sac for the reception of a hernia. (3) Immediately outside the external abdominal ring at the upper part of the scrotum; in which state, when a hernia descends, it passes in front of the testis into the scrotum, even as low as its fundus. A defective development of one or even both sides of the scrotum is associated with these otherwise defective conditions; and thus the Surgeon may be led to discover an abnormal position of the testis, a matter of great importance as to the appropriate treatment of any such modification of congenital hernia—*i.e.*, inguinal or scrotal herniæ, with *undescended testicle*.

The *abnormal conditions of the vaginal process* of peritoneum, in connexion with the abnormal situation of the *testicle*, and the relative position of the *hernia* to this organ; may be thus tabulated:—

(1) The vaginal process continuing open and common to the cord and testis.

The testis may be situated—

- a. in its normal site at the fundus of the scrotum;
- b. just outside the external abdominal ring, or between its pillars;
- c. within the inguinal canal;
- d. within the abdomen.

N.B. In *a*, *b*, *c*, the hernia is generally in contact with the testis; in *d*, it is not.

(2) The vaginal process of the cord and testis communicating by an intermediate aperture.

The testis in the scrotum.

N.B. The hernia may or may not pass through this aperture, and is therefore sometimes but not always in contact with the testis.

(3) The vaginal process of the cord only being open—Hernia into the funicular portion of the vaginal process. So named by Birkett, this condition was first described by M. Malgaigne.

The testis in the scrotum.

N.B. The hernia is never in contact with the testis.

*Additional sacs*, or prolongations and extensions of the vaginal process within the abdominal walls;—"intra-parietal," "inter-muscular," "interstitial, hernial sacs;" "*hernie-embissac*" of French authors. Concurrent with misplaced testis there may be an abnormal disposition of the hernial sac, itself abnormal. An offset from the vaginal process of peritoneum, forming a second sac, may extend into the substance of the abdominal wall. The hernial sac will thus consist of two parts; that division which passes along the inguinal canal into the scrotum, and that

In congenital hernia, scrotal or inguinal, with *undescended* testicle; the absence of this organ from its normal situation will declare the nature of the hernia. The testis may be found just outside the external abdominal ring or between its pillars; within the inguinal canal; or within the abdomen. Still, in the first two modifications of congenital hernia, the hernia is generally in contact with the testis; in the last named it is not so. An *inflamed* undescended testicle simulates the symptoms of strangulated hernia; thus obscuring the diagnosis of these two conditions,—orchitis and congenital hernia presumably strangulated. In the inguinal canal; the tumour, having an oblong shape, may be tense and painful, with some abdominal tenderness emanating from that situation, and there may be perhaps nausea and constipation. But if it be the orchitis of a misplaced testicle, these symptoms subside after a while, and especially the constitutional disturbance; leaving only a tumour of diminished size, the testicle, in the inguinal canal. And the absence of this organ from the scrotum will have suggested, in the first instance, the probable nature of the case. I remember, when a student, having seen such a case under the care of Mr. Erichsen, soon after he joined the University College Hospital. In any case of supposed congenital or infantile hernia, the duration of the tumour from childhood, in some instances, will throw some light on the question of diagnosis.

*Encysted* hernia presents no distinctive characters from congenital hernia; but the testicle can be felt distinct from the hernial contents, at the bottom of the scrotum. The precise nature of the hernial tumour is, however, usually discovered only during an operation, when requisite for the relief of strangulation.

DIAGNOSIS OF INGUINAL HERNIA.—Every inguinal hernia escapes from the abdomen above Poupart's ligament.

*Femoral hernia* is distinguished as follows. When inguinal hernia is confined to the inguinal canal—as an incomplete hernia or *bubonocoele*, Poupart's ligament can always be traced along its inferior border, and the hernial aperture is situated above this ligament. Thus the tumour is distinguished from femoral hernia, which is situated below the ligament, and this band can always be traced along the superior border of the tumour. When the hernia has become *scrotal*, it will have escaped through the external abdominal ring, the outer pillar of which is attached to the spinous process of the pubes. Placing the point of the finger on this process; if the neck of the tumour lies internally—between the finger and the symphysis pubis, the protrusion must have passed through the external abdominal ring, a demonstration of its being of inguinal origin. A hernial tumour situated to the outer side of the finger, will probably have passed through the crural ring, and thus be a femoral hernia.

*Chronic tumours* in the inguinal region and scrotum respectively, may, with regard to their diagnosis from inguino-scrotal hernia, be divided into two classes; reducible and irreducible tumours.

*Reducible* tumours are; (1) inguinal hernia, (2) hydrocele of the vaginal process of the p.-ritoneum, (3) hydrocele of the funicular portion of the same process, (4) varicocele of the spermatic veins.

*Irreducible* tumours may be either fluid or solid, or mixed solid and fluid. The fluid are; (1) hydrocele of the tunica vaginalis propria testis, (2) hæmatocele in the same sac when first developed, (3) encysted spermatocele connected with the epididymis, (4) hydrocele of the spermatic cord. The solid, or solid and fluid, are; (1) diseases of the testis (a) of

inflammatory origin, (b) specific new growths; (2) old hæmatocele, (3) diseases of the spermatic cord, (4) growths of fat extending from the inguinal canal into the scrotum, (5) diseases of the tissues of the scrotum. All these diseases, presenting swellings or tumours, are described in other parts of this work; it will here suffice to notice their points of difference from inguino-scrotal hernia, which may be conveniently exhibited in a tabular form.

THE REDUCIBLE TUMOURS.	
<i>Their entrance or return into the abdomen.</i>	
	<div>Characters in common.</div> <div>Special Characters, when uncomplicated.</div>
1. Inguinal Hernia.	<p><i>All</i> return into the abdomen most easily when the patient lies recumbent, and the abdominal muscles are relaxed.</p> <p>1. <i>Hernia</i> enters most readily. When once commenced, passes in quickly and suddenly. Entrance complete. Thick and opaque neck of tumour. Testis may or may not be perceptible until reduced. <i>No</i> vibration.</p>
2. Hydrocele of vaginal Process of Peritoneum.	<p>2. <i>Hydrocele</i> of vaginal process of peritoneum enters slowly, and never suddenly. Entrance complete. Narrow and translucent neck of tumour. Testis imperceptible until the fluid has entered the abdomen. Vibration.</p> <p><i>Their Passage from the Abdomen.</i></p> <p><i>Special Characters.</i></p> <p>1. Is developed from above, descends when the patient rises or exerts the abdominal muscles, and more quickly than others. Pressure over the ring prevents its descent.</p> <p>2. Seems to be developed from below upwards. The serous fluid sometimes remains when patient is recumbent.</p> <p>3. Similar to No. 2.</p>
3. Hydrocele of funicular portion of vaginal process of peritoneum.	<p>3. <i>Hydrocele</i> of funicular portion of vaginal process enters like No. 2. Entrance complete. Translucent. Neck of tumour may pass into inguinal canal. Testis perceptible at fundus of tumour. Vibration.</p>
4. Varicocele.	<p>4. Varicocele enters very slowly. Entrance not complete, the bulk of tumour only diminished. <i>No</i> vibration.</p> <p>4. The tumour increases like hernia when the patient rises; but it increases also if pressure be made over the course of the spermatic veins in the inguinal canal, or by retardation of the blood however caused.</p>

## THE IRREDUCIBLE TUMOURS.

<i>Disease.</i>	<i>Weight.</i>	<i>Translucency.</i>	<i>Fluctuation and Vibration.</i>	<i>Relation of Testis to Tumour.</i>	<i>Figure and Development.</i>	<i>Size.</i>	<i>Consistence.</i>	<i>Pain.</i>
<b>Hernia.</b>	Lighter than either the fluid or solid tumours.	Very rarely so; generally opaque.	Only when fluid co-exists with the hernia.	Position variable, but the testis usually discoverable.	Pyiform, but with thick neck. Occasionally globular or ovoid. Outline regular. Begins at neck of scrotum and descends.	Variable; at times very large.	Soft and yielding, except it be omental.	Painless unless eased.
<b>Fluid Tumours.</b>	Hæmatocele rather heavier than hydrocele.	Hydrocele particularly so. In rare cases opaque. Hæmatocele opaque.	Distinct vibration very characteristic as in hydrocele.	Perceptible in spermatocele; not in hydrocele of tunica vaginalis propria testis, usually.	Pyiform, but with very thin neck. Outline very regular. Globular as hydrocele of spermatic cord. Oblong as in spermatocele, and nearly transverse to vertical axis of scrotum. Begin near fundus of scrotum and ascend.	Rarely very large.	Yielding and elastic. Exceedingly incompressible as hydrocele of cord.	Painless unless testis be squeezed, usually.
<b>Solid Tumours.</b>	Generally heavier than fluid.	Opaque.	Absent.	Often involved and imperceptible, though its site may be discoverable by pressure.	Outline of testis often preserved. Sometimes surface irregular.	Large; steadily increasing.	Resisting, firm, and rarely hard.	Painful, but varying in degree.
<b>Mixed Tumours.</b>	Heavy.	Sometimes in parts of them.	In some parts, not in others.	Involved.	Irregular Outline.	Large; at times rapidly increasing.	Resisting in parts, soft in others.	Variable.

**TREATMENT.**—Inguinal hernia, in common with other herniæ, requires different treatment according to whether it be reducible, irreducible, or strangulated; besides which there is the special adaptation of treatment to the special varieties known as congenital and encysted herniæ.

*Reducible hernia* should be returned, as soon as possible, by employment of the taxis; care being taken that this manipulation of the tumour be conducted gently, in the manner already fully described. The direction of pressure is particularly important; and the terms oblique and direct with regard to inguinal hernia, will sufficiently suggest the course of the hernial protrusion. When reduced, a suitable and well-fitting truss must be applied and worn. The pad must be so adjusted as to fairly close the hernial aperture; in the oblique inguinal, it should press not only upon the external abdominal ring, but also upon the whole length of the anterior wall of the inguinal canal; in the direct inguinal, the external ring only need be closed. Some pain or discomfort, owing to pressure on the spermatic cord, may require a little readjustment of the truss.

*Inguinal hernia Trusses.*—Various forms of Truss have been invented, and used, for Inguinal hernia. Those which are more commonly employed differ in their construction, and relative advantages, as follow :— (1) Salmon and Ody's truss—Its peculiarities are; (a) the spring extends from the centre of the spine across the abdomen to the abdominal ring—the truss being of formed, that it passes round the opposite half of the body to that on which the hernia occurs. (b) The pad is attached to a ball-and-socket joint, so that it may more accurately follow the movements of the trunk. Fig. 400 represents the *single* truss, of this description; (Fig. 401) the *double* truss, or that for double inguinal hernia.

FIG. 400.

FIG. 401.

Salmon and Ody's truss is a most efficient form of support; I have used it successfully where other inguinal trusses have failed; its special advantage being the *immovable* pad. (2) Coles' truss, differs little from the preceding, in the spring; but it is applied to the side of the body on which the hernia occurs. The speciality of construction, as patented, is, however, in the pad; it is pear-shaped, and contains within it a flat,

helical spring, which acts as the ball-and-socket joint, but retains the pad more accurately fixed against the internal abdominal ring (Fig. 402). The strap around the waist, as here depicted, is an exception; it having been adjusted, by Mr. Bigg, for a patient with an abscess just above the hip-joint; where the slightest touch could not be borne on the part subject to the pressure of an ordinary Coles' truss. This also is a most efficient truss, especially perhaps for inguinal hernia of *larger* size, where the abdominal rings are more open; but—allowing the more favourable shape of the pad for this special purpose—the action of the helical spring tends to bury the pad and thus dilate the internal abdominal ring—the aperture of protrusion; and, I do not find the pad so freely moveable in accordance with the ever-varying movements of the trunk, in walking, or riding on horseback. (3) Tod's truss, has two peculiarities of construction; a spring which passes *over* the crest of the ilium, and not below it across the buttock—thereby, apparently exercising a more direct control over the internal ring; and, a diminished size of the pad. The former supposed advantage, is, I think, sufficiently provided for by the ball-and-socket joint over the pad—without the specially oblique position of the spring; and, the latter peculiarity, a smaller-sized pad, is a positive disadvantage, by tending to bury itself and thus enlarge the internal ring.

FIG. 402.

(4) The *Moc-Main* truss, is a *lever-truss*, and Bigg's *triple-lever* truss, another of the same kind of instrument; inguinal lever-trusses. The former, consists of a padded leather pelvic band and a large oval pad. But, the pad is stuffed with floss silk, in the midst of which a small metal lever is placed. A thigh-strap is attached by one extremity to this lever, and controls its action when the truss is in use. The advantage of this instrument is its flexibility, whereby it can be worn when necessary to con-

FIG. 403.

control a hernia in the night as well as the day; but, as the sitting-posture loosens the spring by diminishing the tension of the under-strap, the support of this truss is insecure excepting during perfect rest. Bigg's *triple lever-truss*, brings three lines of force to bear on the hernial ring, and is thus specially fitted for exceptional cases of inguinal hernia, which cannot be controlled or supported by previously described trusses.

*Scrotal hernia Truss* presents two peculiarities of construction. It is formed of a padded pelvic spring, as in other trusses, but the pad, instead of being pear-shaped or oval, is *fusiform*; and the lower prolongation is attached to a *perineal* strap (Fig. 403). This strap being carried round the posterior part of the thigh opposite to the rupture, and fastened to the pelvic spring, keeps the pad firmly fixed along the whole length of the inguinal canal; and guards also the external abdominal ring. Thus,

then, both inguinal protrusion, and its continuation as scrotal hernia, are prevented.

On looking at the various forms of Truss, above described; it will be seen that they differ somewhat, in the *pelvic spring*—as to its direction—transverse or oblique; but, the principal peculiarity of each consists in the *pad*—as to its shape, oval, pyriform, fusiform, its immobility, by a ball-and-socket joint or helical spring, and its further adaptation by padding. In regard to this last particular, may also be mentioned other pad materials—the *sand-pad*, and the inflated-pad, with *air* or *water*.

*Radical Cure.*—The ancient or even the less older methods of procedure, now obsolete, may justly be passed over unnoticed. Such were the applications of various ointments, plasters, the actual cautery, caustics; royal stitch, punctum aureum, excision, or ligature, of the sac; ligature of the sac without including the spermatic cord, with or without excision, as practised by Schmucker and Langenbeck; and obliteration of the neck of the sac by the pressure of a strong tight truss, as recommended by Richter and L'Estrange. The modern operations are those of Schuh, Rigg, Belmas, Velpeau, Pancoast, Bonnet, Gerdy and Signoroni, Wurtzer, and John Wood of King's College Hospital. Of these operations it will suffice to notice more particularly those of the last three named authorities; and the following summary of them all is gathered from Mr. Wood's original Treatise on Rupture.

The operations may be classed under two heads. *First*—those which deal with the interior of the *sac only*, with the view of causing *adhesion* of its opposed surfaces to each other; upon the principle of the radical cure of hydrocele. This has been attempted in various ways—namely, by a simple seton of threads, candle-wick, or sponge, passed through the sac by a needle or other instrument. Such are, briefly, the methods practised by Schuh of Vienna, and Riggs of New York. Belmas of Paris, passed into the interior of the sac a bag of goldbeater's skin, which was then distended with jelly to induce irritation of the sac. Velpeau in Paris, and Pancoast in New York, injected into the sac a solution of tincture of iodine or cantharides.

Assuming that these methods of obliterating the sac are without peril to the life of the patient—which for many of them, is a very liberal concession indeed—a simple adhesion of the surfaces of the sac itself, will not prevent the formation of another sac from the abundant and loose peritoneum of the internal opening; the real, effective boundaries of the inguinal canal and rings being left as patulous as before. This was long ago pointed out by Lawrence in his able treatise on Ruptures. With this class may be associated the operative procedure of Bonnet of Lyons, which consists in passing needles across the sac and its coverings; thus pinching them up, as they emerge from the superficial ring. The anterior part only of the sac, and below the inguinal canal, is regarded in this procedure; leaving the upper and posterior portions, and the tendinous boundaries unaffected. The result is the temporary retention of the hernia in the canal, and an ultimate return to its former condition; with the further disadvantage of a constriction or incomplete adhesion, opposite the point operated on, which increases the liability of strangulation. The ultimate condition of the parts was invariably unsatisfactory.

The *second* class of operations are based upon a different principle—*invagination* of the skin and fascia of the scrotum, so as to form a plug up the hernial canal.

*Gerdy's method.*—The skin of the scrotum, containing some portion of the fundus of the hernial sac, is pushed up into the superficial ring upon the finger of the operator. A curved needle, armed with strong ligature thread, is then carried along the finger, and thrust through to the surface of the groin on each side of the point of the finger. The ligature is then tied up, so as to hold the invaginated sac and skin in their new position, till adhesion has taken place in the interior of the canal. Signoroni used a piece of catheter for invaginating; while Gerdy attempted further, to cause adhesion of the opposed surfaces of the hollow cone of skin by removal of the cuticle by caustic ammonia, and by placing sutures at the mouth of the invagination—a proceeding which was usually futile.

*Wurtzer's method.*—In this modification of the operation by invagination, the fore-finger is first introduced to push up the integuments and fundus of the sac through the external abdominal ring and inguinal canal, as high as the internal ring; a box-wood hollow plug is then introduced, as the finger is withdrawn, and a long flexible needle passed along its interior is thrust through the invaginated skin and sac, thence outwards through the anterior wall of the inguinal canal. A grooved piece of wood is then laid over that part, and held in position by the projecting point of the needle at its extremity, while the lower end is fixed by a screw to the plug, so as to compress the invaginated integument and sac. The object is, to distend the inguinal canal and rings by the plug, and to compress by the screw; thus to induce adhesive inflammation between the opposed surfaces of the invaginated integument and sac up to its mouth. In this way by preventing the unfolding of these parts, a permanently inverted cone may result, closing up the hernial canal. Hence the plug is retained for an apparently sufficient period for this purpose, usually about seven days. This procedure, originating with Wurtzer of Bonn in 1838, followed by Rothemund in Munich, and Sigmund in Vienna; was introduced into this country by Mr. Spencer Wells in 1854, and subsequently advocated by Redfern Davies, and others. Mr. Davies suggested that the plug should be made to expand like a glove-stretcher, so that it may fill out the internal ring.

The failure of all these operations is not due to peritonitis; when a fatal result has ensued, it has generally been owing to suppuration and the burrowing of matter between the abdominal layers, and sometimes consequent on pyæmia. But, either mode of operation by invagination commonly proves ineffectual for a complete and permanent cure. In Gerdy's 36 cases, most if not all had a relapse of the hernia. Wurtzer's method seems to have been, from Mr. Wood's inquiries, entirely unsatisfactory in its results. With very few exceptions, the rupture re-descended soon after the plug was withdrawn, or whenever the constant use of a truss was discontinued. A very general impression—he adds—prevails among Surgeons, both in this country, in France, Germany, and the United States, that none of the foregoing operations have given such promise of satisfactory results as to bring them into general use.

*Wood's Operation.*—The novel principle originated by Mr. Wood, for the radical cure of inguinal hernia, consists in the compression and closure of the tendinous sides of the hernial canal throughout its *entire* length; this principle prevailing in the various methods proposed and practised by this author. Thus characterized, they differ entirely both from the older and more modern operations; all of which either deal with the sac

almost solely, or rely upon the principle of dilatation or plugging of the canal. Moreover, unlike that of Schmucker, Langenbeck and others, Wood's operation is of an entirely subcutaneous character. The sac, if punctured at all, is pierced by a small and valvular opening only, and remains deep-seated away from exposure. And the connexions between the sac itself and the layers of deep-seated tissues, are not broken down or interfered with, being traversed only by the needle and ligature.

*Instruments.*—The operation, as practised by Mr. Wood, requires certain instruments (Fig. 404); a small tenotomy-like knife, a stout un-

FIG. 404.

yielding curved needle mounted in a strong handle, a piece of stout copper wire silvered about two feet long, or a stout hempen thread of sufficient length well waxed and then soaped, and a compress of box-wood, glass, or porcelain, long and broad enough to cover the hernial canal. Wire is usually selected, and the operation is performed in the following manner, under the influence of chloroform to relax the abdominal muscles.

The patient lying recumbent with his shoulders well raised, and the pubis and scrotum cleanly shaved; the Surgeon will find it most convenient to stand on the side of operation, and to invaginate with the fore-finger of the right hand on the right side, and *vice versa*. The hernia having been carefully and completely reduced, an assistant should command by pressure, the internal ring, if there be any tendency to protrusion. An incision is then made with the tenotomy-knife, through the skin of the scrotum, over the fundus of the sac, and in direction, obliquely downwards and outwards (Fig. 405); the length of this scrotal incision being sufficient to easily admit the point of the fore-finger with the needle. If the hernia be a bubonocoele, the seat of the scrotal incision should be one and a half

inches below the spine of the pubis. The knife is next turned flatwise between the skin and the fascia, and carried subcutaneously around the edges of the incision, so as to detach the one from the other over an area

FIG. 405.

of at least two inches in diameter; or to a wider extent in a large hernia. Now, the knees of the patient should be brought together and bent up to

relax the inguinal structures; the operator's fore-finger is then passed, with the nail backwards, into the scrotal aperture (Fig. 406), and made to invaginate the detached fascia into the inguinal canal, invagination being commenced at as low a point as possible, so as to force the finger as much as may be behind the hernial sac between its fundus and the spermatic cord, and passed up as high as possible in the canal towards the internal abdominal ring. Hooking the finger well towards the surface, the lower

FIG. 406.

border of the internal oblique muscle will be felt raised upon it (Fig. 407), and more distinctly recognised by placing the other hand upon the surface of the groin. By directing the finger inwards, the conjoined tendon, raised with the muscle, will be felt at the thumb side. The needle unarmed, and oiled, is then passed along the same side of the finger, and pushed through the tendon, then obliquely upwards and inwards through

the internal pillar of the external ring, till the point is seen to raise the skin of the groin; and this manœuvre should be carefully preceded and covered by that of the finger. The skin is drawn in the same direction,

FIG. 407.

obliquely upwards and inwards, as far as its attachment will allow, and the point of the needle made to emerge (Fig. 408). One end of the wire

FIG. 408.

is then connected with the eye of the needle, and the instrument withdrawn by a quick jerk, carrying the wire in its course, after it, out through the scrotal aperture, the other end of the wire projecting through the puncture above. Directing the invaginating finger behind the external pillar of the ring to opposite the internal ring, as close as possible to Poupart's ligament, in the groove between the spermatic cord and the ligament; the needle carrying the ligature, is passed along the curve of the finger, and pushed through the aponeurosis of the external oblique at the above point (Fig. 409), when the skin is drawn upwards and outwards until the needle can be brought through the puncture before made. A loop of the ligature is then left in the puncture, and the needle withdrawn, carrying the free end. In the operation as more *recently* practised by Mr. Wood, the needle is *disengaged* from the wire, when withdrawn from the scrotal aperture—after making the puncture through the conjoined tendon; and, then it is passed *unarmed*, in making the second puncture, through the aponeurosis of the external oblique at Poupart's ligament. The opposite end of the wire there projecting, is then connected with the eye of the needle, and drawn through the puncture in the course of the needle, out through the scrotal aperture; and the instrument is again disengaged.

FIG. 409.

Thus, two ends of wire emerge together from the lower or scrotal aperture, after traversing the conjoined tendon and internal pillar on the inner side, and Poupart's ligament at the outer side; while the loop connecting them, emerges at the upper or groin aperture.

The sac of the hernia and investing fascia opposite the scrotal aperture, is then pinched up between the finger and thumb, and the spermatic cord slipped back, as in the operation for tying the veins in varicocele. The needle is then passed from without inwards and slightly upwards in the direction of the incision, across the scrotum, close to and in front of the spermatic cord; the needle entering and emerging entirely within the limit of the scrotal incision. If, however, the skin be accidentally punctured, the incision may be extended to meet that point. One of the ends of wire, the inner more conveniently for the purpose of compression, is then again hooked on to the needle, and drawn with it across the cord through or behind the sac, traversing the scrotal fascia (Fig. 410). Then, the ends of the wire are to be drawn down, until the loop above is close to the skin; here it is fixed by the finger of an assistant, while the Surgeon twists the ends round each other, giving them three or four turns. This manœuvre twists the enclosed sac and fascia which are held between the ends of the

wire. Lastly, the loop is drawn steadily upwards, so as to invaginate the twisted sac and scrotal fascia firmly into the inguinal canal, up to the internal abdominal orifice. The loop is then, in its turn, twisted well down into the upper or groin aperture, giving it the same number of turns. Certain manipulations will enable the operator to determine whether all is secure; by placing his fore-finger in the scrotal aperture, he may judge whether the external ring is closed satisfactorily by the tightening of the wire, and the effect of traction on the wire upon the posterior wall can also be distinguished. Great care should also be observed that the scrotal skin is not drawn upwards between the pillars of the ring, which would prevent their direct union. The projecting ends of wire are cut off by

FIG. 410.

FIG. 411.

pliers, about three inches from the surface, and hooked up under the loop; both forming an arch over the intervening skin. A roller is then lodged beneath the arch (Fig. 411, c), and a broad spica-bandage applied to make firm compression upon the roller, as steadied by the arch of wire.

The period for untwisting the wire is about the eighth or tenth day, and it may be removed about the fourteenth, or as late as twenty-one days when consolidation takes place slowly. A truss must be worn eventually, and Mr. Wood recommends the horse-shoe pad truss, of sufficient strength to support, but not to compress, with a pad formed to make flat pressure, and over the neighbouring parts as well as the obliterated canal. Cases have been treated entirely without truss.

The results of this operation give the encouraging proportion of 65 to 70 per cent. of successful cases; without reckoning doubtful and imperfect cases, and with a fair allowance for imperfect records and future casualties. This average percentage is also drawn from entirely unselected cases, as presented; oblique and direct, good and bad, many of them of

a very aggravated kind, some of enormous size, and treated by operative procedures some of which were more or less tentative.

*Irreducible hernia.*—Inguino-scrotal hernia, when irreducible, often attains a large size. It must be supported in a bag-truss, and thus also somewhat protected from injury.

*Strangulated hernia.*—The operation for liberating inguinal hernia, at the seat of stricture, and thence returning the visceral protrusion, is conducted in accordance with the procedure already noticed in the general treatment of Hernia.

This operative procedure may be described as follows:—the patient lying on his back, and under the influence of chloroform, and the parts having been shaved; an incision is made in the course of the neck of the tumour (see Fig. 398), by pinching up the skin transversely about opposite the external abdominal ring and transfixing the fold. Any small bleeding arterial vessel had better be secured by a pinch or twist with the forceps, so as not to obscure the dissection. Then, cautiously dividing the superficial fascia and other coverings, by using the scalpel with a lateral, scraping action, or even more cautiously, by dividing the textures successively on a director; the sac is soon reached below the external ring, or above that point,—on thus dividing the tendinous aponeurosis of the external oblique. Rarely, the cord lies in front of the sac; if so, it must be drawn to one side, out of the way. The sac is recognised by its appearance; thin and translucent, and transmitting the colour of its hernial contents, in recent hernia; thick and opaque-white, in old hernia.

The seat of stricture is then sought for, as it may be found perhaps external to the sac;—either at the external abdominal ring, the border of the internal oblique muscle, or most frequently, at the internal abdominal ring,—in oblique hernia; or at the external ring, the margin of the conjoined tendon when ruptured, or most frequently, at the mouth of the sac,—in direct hernia. If situated at either of the more superficial points, with regard to either form of hernia, the stricture can be divided *external* to the sac; and then sometimes the hernia becomes reducible. Otherwise, the seat of stricture being *internal*, as it usually is, or if the symptoms of strangulation have been persistent; the sac must be opened, and in the ordinary manner. By carefully nipping up a small portion with the forceps and using the knife flatwise, a small button-hole incision is made; this aperture is then enlarged by slitting the sac upwards and downwards, cautiously, on a broad hernia director, and with a probe-pointed bistoury. If the director be elevated so as to stretch the sac over it, there will be scarcely any risk of wounding the bowel, which might otherwise overlap the instrument.

The seat of stricture is then again sought for by gently examining the

FIG. 412.

visceral contents of the sac. Situated commonly at the neck of the sac, the stricture must be divided with the *hernia-knife* (Fig. 412), protected

by the finger (Fig. 413). The direction in which it should be used has reference to the course of the epigastric artery. In oblique hernia, this vessel lies immediately internal to the mouth of the sac; in direct hernia, it courses externally. Consequently, the knife should be turned away in the opposite direction, respectively. But, owing to the dragging pressure, inwards, of an old-standing oblique hernia, it comes to simulate a direct hernia,—the artery however, still being *internal*. Hence, the safest direction for using the knife, and dividing the stricture in either form of

FIG. 413.

inguinal hernia, is neither outwards nor inwards, but directly *upwards*

FIG. 414.

(Fig. 414.) This should be observed as an absolute rule, and it is the injunction of Sir A. Cooper and Lawrence. The remainder of the operation, as to the reduction of intestine, omentum, or both, and the management of any adhesions, must be conducted according to the general rules already given.

This operation is more or less extensive, in proportion to the completeness or incompleteness of the hernia; as scrotal, or a bubonocoele. In rare cases, the absence of a sac may perplex the operator; as in inguinal hernia of the cæcum, sigmoid flexure of the colon, or urinary bladder. Reduction cannot perhaps be accomplished, when the stricture is divided, and the protrusion must be left *in situ*; but subsequently, it has sometimes disappeared spontaneously.

In the *female*, the operation is precisely the same; merely substituting the round ligament for the spermatic cord, in the inguinal canal; and the labium pudendi for the scrotum, in scrotal hernia.

*Congenital Hernia* requires a special adaptation of the foregoing treatment, and principally with reference to the situation of the testicle,—as

found in the scrotum, or above the external abdominal ring and perhaps in the abdomen. When, as usual, the testicle has descended into the scrotum, the hernia may be reduced, and a truss applied; which should be worn for a considerable period, not less than two years, in the hope of inducing adhesion of the neck in the inguinal canal—and thus a permanent radical cure. Children, who are naturally restless, and in whom the hernial parts are small, may generally be fitted more conveniently and precisely, with an air-pad truss. When the testicle has not descended, the hernia must be returned as often as it comes down; but no truss should be worn, lest it close the vaginal sheath of peritoneum and thus preclude the descent of the testis.

The radical cure of congenital hernia, by operation, has proved successful. This seems to be the *only* form of inguinal hernia in which Mr. Birkett considers an operation for radical cure to be applicable, and that all other kinds should be rejected as unsuitable. He alleges as the reason for this exclusive selection, the insufficiency of evidence to show that an acquired hernial sac ever becomes obliterated by any process of natural cure, excepting in very rare cases; and that the principle of the radical cure of hernia, by surgical interference, should be and is in fact, an imitation of some such natural mode of cure. It is unnecessary to raise this question further; suffice it to say that the results of the operation for radical cure, Mr. Wood's in particular, are such as to amply justify a more extended recourse to this practice in inguinal hernia,—whether congenital or ordinary hernia.

Strangulated congenital hernia will require an operation for its relief. The peculiarities are; that the stricture is perhaps always situated in the neck of the sac, which must be opened to divide it; the *sac* is the *tunica vaginalis*; it frequently contains a large quantity of serous fluid, clear or dark coloured, and the *testicle* at the bottom of the sac in contact with the visceral protrusion, which may be both intestine and omentum, adherent frequently to the testis. Lastly, division of the stricture may always be directed upwards and outwards with safety; the hernia necessarily being oblique, and lying therefore external to the epigastric artery.

In the *female*, the operation is precisely similar; the hernial descent taking place in the analogous vaginal process of peritoneum, known as the canal of Nuck, which ensheaths the round ligament of the uterus, as it passes down within the inguinal canal.

*Encysted hernia.*—The operation presents the peculiarity of a double sac; an anterior one, the tunica vaginalis, enveloping the true peritoneal hernial sac. The former, therefore, is first opened, exposing a serous cavity but no hernial contents; posteriorly, lies the hernial sac, invested externally by the glistening surface of the opened tunica vaginalis, the conjoined surfaces forming a double serous layer; the hernial tumour, with the testis attached below, is remarkably moveable and readily tumbles out, through the aperture in the tunica vaginalis, as a pyriform mass, suspended only by its attachment to the margin of the external abdominal ring. Proceeding with the operation, the double serous layer is divided, thus opening the hernial sac; which contains, as in other herniæ, intestine, omentum, or both. The stricture will usually be found at the neck of the sac, this is divided and the operation completed by reducing the protrusion.

FEMORAL OR CRURAL HERNIA.—*Course.*—This form of hernial pro-

trusion descends vertically below Poupart's ligament, through the crural ring and canal; lying in the sheath of the femoral vessels, internal to the femoral vein. Emerging from beneath the sharp upper margin of the saphenous opening in the fascia lata,—that portion known as the upper cornu, or the femoral ligament, of the falciform border or process of Burns; the hernia comes forward, anteriorly, through the opening; and then turns upon itself abruptly, upwards, towards Poupart's ligament,—thus overlaying the portion in the crural canal; so that the upper cornu of the falciform border and the crural sheath intervene between the superficial and deep portions of the hernial protrusion. This curved course of femoral hernia is very important in relation to the direction of pressure necessary for reduction; it being requisite that the protrusion should be made to retrace its course; downwards, backwards, and upwards.

*Anatomical coverings, and relations.*—The layers of different textures which femoral hernia receives, successively, in its course from the crural ring, externally, are as follow:—peritoneal pouch forming the sac, subserous cellular tissue or septum crurale over the opening of the crural ring, fascia transversalis forming the anterior portion of the femoral sheath,—which with the septum crurale constitutes the *fascia propria* of Sir A. Cooper; and over the saphenous opening, the cribriform fascia or deep layer of the superficial fascia, with the superficial layer of this fascia containing fat, and then the skin.

These anatomical coverings are interesting in relation to the development of femoral hernia; but as in other forms of Hernia, the coverings become so altered and amalgamated as to lose their importance surgically. To persons who are fond of enumerating hernial coverings, it may be observed that the investments of femoral hernia are essentially the same as those of inguinal hernia, less two; the intercolumnar fascia—and the cremasteric fascia, in oblique inguinal; the intercolumnar and the conjoined tendon, in direct inguinal hernia. While, therefore, either form of inguinal hernia has seven anatomical coverings, femoral hernia has only five; although these may be subdivided anatomically, as if to show their pathological and surgical insignificance.

The relations of femoral hernia to surrounding parts are far more important. The *crural ring*, an aperture of oval shape, and about half an inch wide, is bounded; internally, by the base of Gimbernat's ligament and the margin of the conjoined tendon behind it; anteriorly, by Poupart's ligament with the curved band of the deep crural arch, the spermatic cord, or the round ligament in the female, lying above Poupart's ligament; externally, by the femoral vein with the innermost septum of the crural sheath; posteriorly, by the pubes, its horizontal ramus, covered by the fascia lata,—its pubic portion being prolonged over the pectineus muscle up to the pectineal line of that bone. The position of *vessels* around the crural ring is specially important with reference to the direction in which the stricture of femoral hernia at that aperture may be most safely divided. Commonly, the ring is partially surrounded by vessels; on the outer side, by the femoral vein and at the upper angle by the epigastric artery; anteriorly, the pubic branch of the epigastric runs to the back of the pubes, and more removed from the aperture lie the spermatic vessels of the cord. Thus then, the ring is encircled by vessels, excepting internally and posteriorly. An abnormal origin of the obturator artery may, however, give an additional vascular relation to the ring. Sometimes this artery arises from the (deep) epigastric, and in its course to the notch

in the obturator foramen, it may have either of two positions relative to the ring; passing down more frequently, on the outer side; or arching over and down on the inner side, at the base of Gimbernat's ligament, an occasional course which occurs once in about eighty operations. (Lawrence.) In the one position, the inner side of the ring is still free from any vessel; in the other, it is then completely encircled with vessels, except posteriorly in its relation to the pubes.

The small pubic branch from the epigastric, which runs to the back of the pubes, may perhaps pass downwards near the inner side of the ring to anastomose with the branch from the opposite side; or again, the epigastric artery, having its unusual origin from the obturator or from the femoral artery, may, it is said, ascend under and on the inner side of the ring.

The *crural canal* is the innermost space in the interior of the crural or femoral sheath; the femoral vein, and external to it, the femoral artery, being likewise contained in this sheath. (Fig. 415.) The latter is formed by a prolongation from the fascia transversalis of the abdomen, with a prolongation from the iliac fascia covering the iliacus muscle. Both fasciæ thus named, are only different parts of the same membrane, and are continuous along the line of Poupart's ligament external

FIG. 415.

to the iliac vessels; here, the one passing down in front, and the other behind the vessels, as they become femoral under Poupart's ligament, the two portions of fascia together form a loose funnel-shaped sheath, enclosing the vessels,—in addition to their common cellular investment. This sheath narrows as it continues downwards to about two inches below Poupart's ligament, where its distinctive appearance is lost in the common cellular investment. Its outer border is straight, and perforated by the genito-crural nerve; its inner border is oblique, and appears in the saphenous opening, transmitting the saphena vein and lymphatics. Two very thin septa divide the sheath into three compartments; one septum passes between the femoral vessels, each of which is thus placed in its compartment, while the other septum lies on the inner side of the vein, and defines the compartment known as the crural canal. Its extent is about half an inch in length, reaching only from the base of Gimbernat's ligament to the upper cornu of the saphenous opening. Anteriorly, the sheath forming the canal, is overlaid by the upper cornu of the falciform border of the saphenous opening; posteriorly, is the pectineus muscle covered by the fascia lata, its pubic portion. Externally, is the femoral vein and inner septum of the sheath, already noticed; internally, the sheath alone bounds the canal, owing to the oblique direction upwards of its anterior boundary,—the upper cornu of the falciform process inclining upwards, to join the base of Gimbernat's ligament.

The *saphenous opening*, for the transmission of the saphena vein and superficial lymphatic vessels, is formed by the division of the fascia lata into an iliac and a pubic portion. This opening has an important relation to femoral hernia, in the course of its development. Situated about half an inch below Poupart's ligament, and rather to the inner side of the middle line of the thigh, it is of an oval form, and extends from the superior cornu downwards to the inferior cornu, or about one inch and a half in length, and its width is about half an inch. The inner border is ill-defined, and lies on a plane posterior to the outer margin and the femoral vessels; the pubic portion of the fascia lata, forming this border, passes upwards underneath the sheath of the vessels, over the subjacent pectineus muscle to the pectineal line of the pubis. The outer margin,—falciform border or process of Burns, is anterior to the inner border, it is firmer and well defined, of a semilunar or falciform shape, and its concavity looks downwards and inwards. It is connected by fibrous bands to the sheath of the vessels. The *upper* portion of this firm margin corresponding to the crural canal, has a direct relation to the *development* of crural hernia; and the rigidity of the whole falciform border of the saphenous opening, especially in its bearing on the canal, is much affected by the position of the limb; extension and rotation outwards, having the effect of tightening the margin, while, flexion and rotation inwards, relaxes it. At the saphenous opening, the *inner* aspect of the sheath of the femoral vessels is uncovered; but the opening is closed in by the thin, deep layer of the superficial fascia, which is connected with the margin of the opening, and more firmly with its external or falciform border. This membrane is, however, weakened by the transmission of certain vessels; at the lower part of the opening, by transmitting the saphena vein, and by numerous small apertures in the fascia,—hence named cribriform, for the passage of the superficial lymphatics. Any resistance which the membrane might, otherwise, offer to a hernial protrusion, is lessened by this defective support. The subjacent portion of the femoral sheath is pierced by the same vessels, and weakened accordingly.

When the hernia has escaped through the saphenous opening, and turned up over the crural canal towards the abdomen; its *return* is much affected by the state of the saphenous opening, and of its upper portion in particular.

*Seat of Stricture.*—The strangulation of femoral hernia may be situated; either at the crural ring, and caused by the base of Gimbernat's ligament with perhaps the margin of the conjoined tendon, internally, and Poupart's ligament with the band of the deep crural arch, anteriorly; or, at the margin of the saphenous opening, and caused by the falciform border, its upper corner in particular as it arches over the hernia escaping from the crural canal. These are the situations of stricture pointed out, respectively, by Lawrence and Hey.

Thickened bands of fascia propria, situated about half an inch below the crural ring, across the neck of the sac, may also be an occasion of stricture; so as to constrict and indent the neck. This was noticed by Sir A. Cooper, and it is specially adverted to by Mr. Luke.

*Varieties* of femoral hernia, characterized by the course of the sac, may be here noticed, as being rare and curious. Le Gendre describes four such varieties:—(1) *Pectineal crural hernia*.—The hernia, as soon as it traverses the crural ring, passes directly internal to and *behind* the

femoral vessels, and rests on the pectineus muscle, the aponeurosis of which may form an envelope to it. This is sometimes denominated Cloquet's hernia, he having first described it. Callisen, Vidal (de Cassis), Richet, Le Gendre, and Mr. J. Adams, have recorded similar cases. (2) *Crural hernia, through Gimbernat's ligament*.—This variety is situated internal to the femoral vessels, but it passes directly through the resisting Gimbernat's ligament. It is the hernia of Langier, who first noticed it; and Cruveilhier, Demeaux, Nuhn, and Le Gendre, have also dissected cases of this kind. (3) *Crural hernia, with a diverticulum through the cribriform fascia*.—The hernia traverses several openings in the cribriform fascia, and thus forms several distinct lobes, which give it a very characteristic appearance. This is the hernia of Hesselbach, who first described and figured it; and Le Gendre and Malgaigne have also dissected examples. (4) *Crural hernia, with a diverticulum through the superficial fascia*.—A variety, in which the hernia, having escaped beneath Poupart's ligament and traversed the cribriform fascia, sends one or more prolongations through the superficial fascia. It is the hernia of Sir A. Cooper, and Le Gendre has furnished a dissection and drawing of such protrusion. (5) *Crural hernia, external to the femoral vessels*, is another variety, described by Mr. Partridge as having occurred in one case.

*Signs, and Diagnosis*.—The tumour of femoral hernia presents certain distinctive characters. It is situated below Poupart's ligament (Fig. 416)

FIG. 416.

by about half an inch or the length of the crural canal, and to the inner side of the femoral vessels, but external to the spinous process of the pubes. These relations have reference to the *neck* of the tumour, and femoral hernia may thus be distinguished from inguinal, whether this be a bubonocoele or scrotal hernia. The shape of the tumour is tolerably rounded, and it extends upwards to Poupart's ligament, assuming a transversely elongated form; rarely, it passes downwards upon the thigh. It may attain the size of an orange or larger, though it seldom increases to the size of inguinal hernia. In point of consistence, the hernial tumour will of course vary with the contents of the sac,—as to the presence of intestine, omentum, or both,—an entero-epiplocele, and the quantity of serous fluid in the sac will also affect its tension. But the size of the protrusion materially affects its tension; a small hernia, particularly a knuckle of intestine, deeply seated in the angle between the body of the

pubes and the femoral vessels, presents a tense unyielding lump; while a fully developed, hemispherical hernia has a soft, doughy, consistence. The reducibility of the tumour, and its varying size, according to posture, straining or coughing, and the impulse then communicated; are all additional signs of its hernial nature.

*Females* are much more subject to crural hernia, than males. Perhaps this greater liability may be owing to the larger size of the crural ring in the female. But, as compared with inguinal hernia, the much more common occurrence of femoral hernia, as generally supposed, is not verified by Kingdon's statistics, to which I have already referred. The relation of femoral hernia to *age*, in the female, is remarkable, and explains the numerical equality of the two forms of hernia. Before puberty, inguinal hernia is common, whilst crural is extremely rare. Of 193 girls affected with hernia, before fifteen years of age; 184 were cases of inguinal, and only 9 crural rupture. Even to the age of twenty years, the one is much more common than the other form of hernia; and in a total of 1442 hernial cases in females, at *all* ages from birth upwards, the majority of crural hernia over inguinal was only 54.

After twenty years of age, crural hernia is much more commonly developed than inguinal, and it occurs most frequently between the ages of twenty and forty—*i.e.*, during the prime of life in women. This peculiarity is due to that being the period of life when parturition is also most frequent, whereby the abdominal walls become much stretched and relaxed; and Mr. Kingdon's statistics show that this has a greater tendency to develop crural rather than inguinal hernia. In 680 ruptured women; 262 had the one, 178 had the other form of hernia. The first pregnancy also, has the most predisposing influence, as regards either form of hernia; subsequent pregnancies seem to have an almost invariably declining tendency.

*Diagnosis from other tumours, in the femoral region.*—*Psoas abscess* differs from femoral hernia, in its situation, the characters of the tumour, and its history. The abscess presents below Poupart's ligament, but to the *outer* side of the femoral vessels. It is partly at least reducible in the recumbent posture; and careful palpation with either hand alternately, above and below Poupart's ligament, demonstrates a corresponding subsidence and enlargement, in these situations, as of fluid passing to and fro. The antecedent symptoms of pain in some part of the dorsal or lumbar spine, and constitutional disturbance, will corroborate the diagnosis; any impulse on coughing notwithstanding. *Cysts* occasionally form in the neighbourhood of the crural ring, and associated with hernia, or existing alone. The fluctuation on pressure, with persistence of the swelling and its invariable size; will mainly determine the nature of the case. *Venous dilatation*, or a *varix*, may occur at the saphenous opening. Any such enlargement is reducible like hernia, but pressure above will cause the swelling to be reproduced. The characters of varix are also marked, as to the thrill and murmur, and the varicose enlargement of the vein below the crural tumour. *Enlarged crural lymphatic glands*, may be distinguished from hernia, by the aggregated character of the swelling, and its persistence, and by the absence of any impulse on coughing. The history of the case will also be corroborative. *Fatty tumour*, of small size, and situated in the crural canal, has occasionally been met with. It closely simulates hernia. The soft and doughy character of this growth contrasts with the tense consistence of crural hernia, similarly placed; and the absence of impulse on coughing is also distinctive.

*Treatment.*—This must have reference to the state of the hernia; as reducible, irreducible, or strangulated.

*Reducible femoral hernia*, must be treated in the usual manner; the protrusion returned by taxis into the abdomen, under the influence of chloroform, and a suitable truss applied, and worn, over the crural aperture. The *direction* in which manipulative compression should be made is specially important. Remembering the course of femoral hernia; a fully developed protrusion should be returned by gentle pressure, downwards from Poupart's ligament, in order that it may turn the sharp upper corner of the falciform border of the saphenous opening, then directly backwards as if into the thigh, and upwards, through the crural canal. In short, the hernia is unfolded as it were, and made to retrace its course into the abdomen. During this manipulative proceeding, the Surgeon may avail himself of a relaxed state of the saphenous opening, by flexing and rotating the thigh inwards.

FIG. 417.

The size of the truss-pad should vary with the degree of laxity of the part, and chiefly as regards Poupart's ligament. A small, convex pad will generally prove sufficient support; but a lax state of the ligament will require a larger and flatter pad.

*Femoral Trusses.*—Three principal forms of femoral truss have been devised, which are thus described by Mr. Bigg. All possess the ordinary steel spring pelvic belt. (1) The spring is curved downwards, so as to rest above the femoral region, and is fitted there with a pad, so shaped (Fig. 417) as to exercise pressure just below Poupart's ligament when the patient flexes the thigh upon the body, as in walking or sitting. (2) Another form of femoral truss is furnished with an inflated india-rubber pad. This is admirably suited for old-standing cases; and proves effective, even when the patient is racked with cough or undergoes severe muscular exertion. (3) The pad is self-adjusting, attached to the spring by a steel blade. This variety is useful for horse exercise. When the hernia is of large size, or where it comes down under the fascia lata, it is necessary to use a thigh-belt with a triangular pad projecting on the inner surface; forming a soft continuation of the pad, to fill the triangular space where the cribriform fascia occupies the saphenous opening of the fascia lata.

The hernia rarely, if ever, undergoes a radical cure, in consequence of wearing a truss; thus differing unfavourably from inguinal hernia in respect to this issue, occasionally.

*Radical cure.*—Little has hitherto been done to effect a radical cure of femoral hernia. The operation of invagination into the hernial aperture, was performed in one case, by Dr. G. Jameson of Baltimore, North America; and in another case, with a hard plug retained by sutures, as performed by Mr. Redfern Davies. Both patients survived, but the results with regard to the recurrence of hernia seem to have been very doubtful.

An operation proposed by Mr. J. Wood, but practised only at present, on the dead subject, is performed in the following manner; the instruments used being the same as for inguinal hernia, by the wire operation.

The body lying recumbent with the shoulders raised, a vertical incision about an inch long is made through the skin over the site of crural hernia. (Fig. 418.)

FIG. 418.

The fascia around the margin of the wound is detached subcutaneously to a sufficient extent for invagination, free from skin, fairly into the crural opening. Then, pressing the femoral vein outwards with the forefinger which is used for invaginating, the needle is passed backwards—through the sac were it present—sufficiently deep to take up the pubic portion of the fascia lata covering the pectineus muscle; the point of the needle being afterwards made to emerge in the wound. It is then carried forwards and upwards, and made to transfix Poupart's ligament close to the nail of the invaginating finger. (Fig. 419.) The skin of the groin is drawn outwards, by an assistant, and the point of the needle pushed through it. The wire is then hooked on to the eye of the instrument, and drawn back with it into the wound. Disengaging the needle, leaving the wire protruding, it is passed again through the pubic

portion of the fascia lata, about an inch or three-quarters of an inch—

FIG. 419.

according to the size of the hernial aperture—to the inner side of the

first perforation (Fig. 420); and the point made to pass through Poupart's ligament directly above, and close to the curved border of Gimbernat's ligament, including a portion of its fibres. Drawing the skin inwards until the needle can be pushed through the same puncture before made, and which is already occupied by one end of the wire; the opposite end is hooked on to the needle and drawn back with it, when that end also is disengaged. The two ends of the wire are now twisted down into the incision, and cut off about six inches from the twist. The loop which emerges at the upper puncture is then twisted firmly down in it, pressing down before it that portion of Poupart's ligament opposite the crural opening, which is included in its grasp. A roller of lint, or a boxwood or glass compress of cylindrical form, is applied and secured in position by the ends of wire drawn over it, with pledgets of lint on each side; and over all, a spical bandage.

FIG. 420.

By this operation, that part of the tendinous crural arch which overrides the neck of the sac, is drawn backwards and downwards, so that it may become adherent to the pubic portion of the fascia lata included in the suture. In a large hernia, the sac and its coverings would be transfixed, and embraced in the suture; in a small hernia, the serous sac might easily be returned into the abdomen, and its tendinous investments united altogether external to it. The result might be, that the invaginated fascial and sac-coverings would become adherent on all sides, under the combined influence of ulceration, traction, and pressure; and thus forming a consolidated mass, filling up the area of the crural ring, a radical cure might be accomplished. Its permanency would require the test of time.

Certain parts, contiguous to the operation, should be carefully avoided; the femoral vein,—by interposing the finger between it and the needle during the passage of that instrument; the bowel, the epigastric artery, and in the male, the spermatic cord,—by not pushing the needle too far into the abdominal cavity.

*Irreducible hernia.*—Crural epiplocele very often becomes irreducible, but enterocele in this state is equally rare. No other treatment can be pursued than to support and protect the hernial tumour by a truss with a hollow pad; and this, whether it be epiplocele or enterocele.

*Strangulated hernia.*—Both Pott and Astley Cooper allude to circumstances which are of vital importance in the treatment of crural hernia;

namely, the difficulty often experienced in the reduction of small recently developed enterocele, the rapidly progressive injury to the bowel, and the severity of the accompanying constitutional symptoms. Thus also Mr. Bryant found only 38 cases reducible by taxis, out of 142 cases of strangulated crural hernia admitted into Guy's Hospital. Ten of these cases were herniæ of recent development, and strangulated on their *first* recognised descent. Hence, the Surgeon should always search for a hernial tumour, however unsuspected by the patient. Reduction having failed, and symptoms of strangulation being persistent; an operation for the division of the stricture and liberation of the hernial protrusion, must be had recourse to, as soon as possible. This rule of early operation is no less imperative in femoral than in inguinal hernia.

*Operation.*—The general principles already laid down with reference to operation for the relief of strangulated hernia, are here applicable. In regard to femoral hernia, the stricture may be divided *external* to the sac, and the protrusion returned without opening the sac, and this limited procedure is generally practicable; when *internal*, it will become necessary to open the sac, in order to divide the stricture from within. The patient lying recumbent, chloroform having been administered, the parts shaved, and the bladder emptied; an incision is made by pinching up and transfixing a fold of skin, transversely across the tumour on its pubic aspect, and inclining inwards, so as to reach the seat of stricture. (See Fig. 416.) This latter direction is the special feature of Mr. Gray's admirable modification of the operation—that the incision be placed on the inner side of the neck of the tumour. If the sac be not opened, the operative procedure is thus simply the taxis, plus a slight incision. Other forms of incision are occasionally convenient; a transverse line may be added obliquely, along Poupart's ligament, as thus ; or the inverted  of Sir A. Cooper, or the inverted  of Sir W. Fergusson. The superficial fascia is then divided, and any little hæmorrhage restrained which might obscure the dissection, by pinching or twisting any bleeding arterial vessel. A round tumour is now exposed, having a peduncle curving upwards into the abdomen, at the angle between the body of the pubes and the junction of Poupart's ligament with the spinous process. This is the hernia, but invested with the fascia propria—the femoral sheath of fascia transversalis united with the sub-peritoneal cellular tissue, which may be loaded with fat, and occasionally studded with small cysts. Accordingly, the fascia propria may be thin and membranous; or thickened, and present an almost omental appearance, especially in old-standing hernia long subject to the pressure of a truss. In the one case, the sac lies immediately underneath the fascia; in the other, the sac is buried within its substance. Passing the finger up on the neck of the tumour, the sharp upper margin of the saphenous opening in the fascia lata, may be felt constricting the neck; and immediately behind this, the junction of Poupart's ligament with the base of Gimbernat's ligament may also be the seat of stricture. These strictures should be divided successively; first the falciform border at its upper corner, in order to find the necessity for proceeding a little more deeply to Gimbernat's ligament. Introducing a hernia-knife along the curve of the finger, and insinuating its point between these ligamentous constricting bands and the neck of the tumour, just to within the crural ring; this double stricture can be overcome by dividing it *upwards* and *inwards*—on thus obliquely directing the cutting portion of the knife. It yields with the usual creaking sound and sensation; and a very limited

extent of incision will prove sufficient. Having divided one or both strictures, the hernia may not unfrequently be reduced, without opening the sac, by gently compressing its contents. Sometimes, however, another source of stricture may still exist, in the form of thickened bands of fascia propria, situated about half an inch below the crural ring, across the neck of the sac, constricting and indenting it. These may be divided, as Luke recommends, by insinuating the nail of the finger under them from above, and carrying the point of a probed bistoury along the nail, with its blunt edge towards the sac.

But, if this fails to liberate the hernia, or if the symptoms of strangulation have become thoroughly established, even to stercoraceous vomiting, and the visceral protrusion may have suffered also by prolonged taxis; it will then be necessary to proceed to lay *open the sac*. The fascia propria must first be divided carefully on a director. When thin and membranous, the sac is at once exposed; when thick and fatty, and perhaps cystic, this must be done cautiously, by making more than one layer with the knife and director, lest the sac be inadvertently opened and its visceral contents be wounded. On the other hand, it must be observed not to *make* a sac of one of the artificial layers of the fascia propria, and then, mistaking the true sac for intestine, not to open the hernial sac at all. This latter sac having been fairly exposed, it is opened in the usual manner; a small button-hole incision being made by means of the forceps and knife used flatwise, and the aperture enlarged on the broad director, upwards and downwards; the seat of stricture is then sought for, commonly at the thickened peritoneal mouth of the sac, and this must be divided upwards and inwards, as being the direction of least risk to any vessel adjacent to the crural ring. Sometimes, the ligamentous or fibrous structures external to the neck of the sac having been divided; the mouth of the sac can be sufficiently dilated by gently introducing the point of the finger, without any further use of the hernia-knife. The contents of the sac and any adhesions are then dealt with according to the general rules already given. An entero-epiplocele is usually found; and the omentum lies mostly in front, enclosing and concealing a knuckle of intestine.

Hæmorrhage, perhaps considerable and persistent, is liable to occur in dividing the stricture at the crural ring. This accident is peculiar to femoral hernia, and it has led to a fatal result occasionally, in addition to the ordinary hernial contingency of peritonitis. I have lost one case, owing to the continuance of hæmorrhage internally; and Guthrie states that some of the best Surgeons have lost patients by hæmorrhage after the operation for femoral hernia. It proceeds from the obturator artery, that vessel having its unusual origin from the epigastric artery, and the more unusual course of then arching over the ring and descending on the inner side at the base of Gimbernat's ligament. This vessel will thus be across the knife in dividing the stricture upwards and inwards. Sometimes, it is said, the small pubic branch from the epigastric, running to the back of the pubes, passes downwards near the inner side of the ring to anastomose with the branch from the opposite side; or again, the epigastric artery having its unusual origin from the obturator or from the femoral artery, may ascend on the inner side of the ring. The same liability to hæmorrhage would then occur, in dividing the stricture at the crural ring. Any such unusual source of hæmorrhage, it will be difficult to anticipate or control. Before introducing the hernia-knife, it might be practicable to feel the pulsation of the aberrant artery with the

tip of the finger; or, as Erichsen recommends, the precaution might always be taken of blunting the edge of the hernia-knife, so that the tense fibrous constriction may yield, while the artery is pushed before the blunted edge. When cut, the vessel may perhaps be drawn to the aperture and tied, or twisted at both ends; or the hæmorrhage may be arrested by plugging with lint or sponge, and by cold applications. Secondary hæmorrhage will necessitate a fair exposure of the vessel, by cutting down in the course of the hæmorrhage, and tying whatever vessel bleeds. Occasionally, an artery bleeds which at the time of operation did not; it will then scarcely be justifiable to cut down and explore for an unknown source of hæmorrhage, and the only expedient is a cold application.

A too free division of the stricture at the crural ring, unattended with hæmorrhage, may be followed by an increased liability to hernial protrusion, after recovery from the operation. This result is owing to a weakened state of Poupart's and Gimbernat's ligaments at their angle of junction. The truss, worn after operation, will then require the additional support of a cross tongue, buckled on to its free end.

UMBILICAL HERNIA.—*Exomphalos* or *Omphalocele*, as umbilical-hernia is also sometimes called, signifies a visceral protrusion through the umbilical aperture; in common language, ruptured navel. The *course* of the protrusion, in this kind of hernia, is straight through the abdominal wall.

The hernial sac is always an acquired extension of the peritoneum, there being no process analogous to the inguinal vaginal process of this membrane. Yet umbilical hernia is sometimes described as of two varieties; the *congenital*, with reference to its formation in infants from birth; and the acquired variety, which is developed in *adults*. In the one condition of hernia, the protrusion passes through the umbilical aperture, either before the cord is detached, or before that aperture has closed; in the condition of later or adult life, an aperture is formed by a separation of the fibres of the linea alba at the formerly closed umbilical ring or an immediately adjoining part, in consequence of its having stretched or yielded before the protrusion from within.

The anatomical *coverings* of umbilical hernia are those of the abdominal wall, at the umbilical aperture. Taken from within outwards, in the order of hernial development, they are successively; a pouch of parietal peritoneum or the hernial sac, with sub-peritoneal cellular tissue containing fat, and the fascia transversalis, then a prolongation from the tendinous margin of the aperture, the superficial fascia, and skin. Before the separation of the umbilical cord, the protrusion may pass through the navel-opening, directly into the substance of the cord, which thus forms a peculiar covering to the hernia. In a suddenly produced umbilical hernia, the covering derived from the tendon of the external oblique muscle may be wanting; and the fat, subcutaneous, in the superficial fascia, or that over the peritoneal investment may have disappeared. All the coverings are often inseparably united together, so that the common covering is frequently very thin, and the contents of the sac become more or less perceptible. The umbilical aperture forms a very firm and unyielding tendinous margin around the neck of the sac, itself somewhat thicker at this part than over its expanded part or body. The mouth of the sac is often large in proportion to the bulk of the protrusion. As the hernia increases in size, the varying anatomical relation of the umbilical aperture

becomes important. The tumour does not extend uniformly upon the anterior surface of the abdomen, but downwards towards the symphysis pubis more than in any other direction. Occasionally, the transverse diameter of the tumour exceeds the vertical, or it may be pyriform and suspended by a peduncle or stalk. Sometimes, it is sessile, with a base almost as large as its body; or it may be only apparently so, and when elevated presents a small stalk, thus resembling a mushroom in shape. The visceral contents of umbilical hernia are, commonly, both intestine and omentum—an entero-epiplocele; and in a large hernia, nearly the whole intestinal canal, small and large intestine, may be found enveloped by omentum. The latter sometimes becomes firmly adherent to the sac, or bands are produced by which the intestine becomes entangled; while by hardening and contraction of the omentum, this portion of the protrusion forms anomalous masses within the sac. Other viscera, occasionally, are included, as the stomach, or uterus; in one case, Murray found that the gravid uterus, at the eighth month of pregnancy, formed the contents of an umbilical hernia.

The *stricture* in this kind of hernia, is the firm margin of the umbilical ring.

Certain *signs* in connexion with the tumour are characteristic. The hernia commences as a small soft, projecting ovoid tumour, at the navel. (Fig. 421.) It gives a distinct impulse on coughing, but is readily re-

FIG. 421.

ducible by gentle pressure with the finger; and a small aperture is then felt, having a firm sharp border. On removing the finger, the skin remains relaxed and creased in the fossa of the navel; or it unfolds and distends, until the tumour reappears as before. As the hernial protrusion increases, the tumour assumes other forms, according to the anatomical relations of the umbilical aperture, in point of its size and position with regard to the protrusion. Hence a pendulous tumour is presented, semi-lunar transversely, or pyriform, with the aperture towards its upper part; or a round, flattened, and sessile, or nearly stalkless tumour.

Umbilical hernia often attains a large size, and an irregular shape as if consisting of several tumours, owing probably to the yielding of its fascial or tendinous coverings at different parts; it has also a partly doughy and tympanitic consistence, according to the visceral nature of its contents. When adhesions to the sac have taken place, the tumour is proportionately irreducible.

This kind of hernia occurs mostly in infancy, at birth before the cord is detached, or before the umbilical aperture has closed; or in adult life, and indeed at any period of life; and in both sexes. Females are most liable, and especially those who have borne many children, or have a tendency to abdominal obesity.

The immediate cause, as in other herniæ, is some straining effort of the abdominal muscles; as by the act of crying in children, coughing or parturition in adults and females.

*Treatment.*—*Reducible umbilical hernia* should be returned, and a proper support worn over the hernial aperture. In infancy, an elastic india-rubber belt with an air-pad, is most effectual; or a simpler and more ready contrivance, is a slice of cork covered with leather, so as to form a firm, flat, compress over, not in, the aperture; and retained by cross strips of plaster and a broad circular bandage. Thus supported, the aperture has a strong natural tendency to close. In adults, a suitable truss must be worn, made on the same principle as for the hernia in infancy. The annexed figures represent the most appropriate forms of Truss; a broad elastic bandage, of such width as to support the whole weight of the abdominal viscera, and carrying a pad which rests upon the umbilical aperture and localizes the force there. (Fig. 422.) Another

FIG. 422.

form, suited for severe cases, is a lightly constructed steel-truss. (Fig. 423.) The *radical cure* by operation has been performed by Mr. Wood, in three obstinate cases. He applied a small pair of rectangular pins vertically, and in opposite directions, one on each side of the opening, transfixing the edge of the tendinous aperture, and making them emerge close to each other through the integuments above and below the opening. When locked into each other, and twisted, the edges of the aperture

FIG. 423.

were drawn close together in a line with the linea alba, so as to protrude the integuments and sac of the rupture in a vertical fold above them. The pins were surrounded, and the skin protected, by strips of lint and plaster, and were retained four days, without any unpleasant symptoms. They were then withdrawn, and the edges of the aperture had firmly united. A pad and circular bandage were used for a short time, and the child was then discharged from the Hospital. While under observation, no return

of the rupture had occurred. An *invaginating* operation has also been performed by the same Surgeon, on the principle already fully explained with regard to inguinal and femoral herniæ. The details of this procedure are given in Mr. Wood's Treatise. Respecting its applicability, it is said that, in favourable cases of umbilical hernia in the adult, this operation may be tried with but little danger, considerable probability of success, and the certainty of not rendering the state of things worse by interference. Other Surgeons have successfully effected a radical cure by operation; Mr. Barwell on three patients at the respective ages of six months, fifteen months, and eight years; Mr. H. Lee has also cured cases on the plan of the operation already described; and Mr. C. Heath, in a case of strangulated umbilical entero-epiplocele, having returned the bowel, he dissected the sac away and passing a ligature through its base and the omentum, these were then removed. Recovery ensued, and some time after no hernial protrusion had recurred. But considering the strong tendency to a natural cure, in *infancy*, when the abdominal aperture is properly supported and for a sufficient period; it will always be a serious question whether any cutting operation is justifiable?

*Irreducible* umbilical hernia must be treated on the usual principle of support and protection by means of a bag-truss.

*Strangulation* rarely arises. The symptoms of obstruction and nausea or vomiting, may be those of incarceration, and are mostly dependent on a flatulent and loaded state of the intestinal canal; and this can generally be overcome by purgatives and enemata, with re-employment of the taxis a second and a third time, at intervals of two or three hours. On the other hand, the symptoms of true strangulation are very insidious in umbilical hernia, especially when the tumour is old-standing and irreducible. Consequently, timely recourse to operation must not be overlooked.

The operation is very simple. An incision in the middle line over the neck of the tumour, and to about two inches in extent, will generally suffice to reach the constriction at the umbilical aperture. The fascial coverings should then be carefully divided as the sac is soon reached; the finger-nail is inserted under the firm margin of the aperture, and the stricture slightly divided upwards, without opening the sac, and the hernia returned into the abdomen; or, if reduction cannot thus be effected, the sac must be opened, and the constriction divided within, upwards in the same line as the first incision. The omentum and bowel are then managed on general principles. Any other situation around the neck of the tumour may be selected for operation, when more convenient with regard to the position of the neck; and the stricture may be safely divided at any such point in the circumference of the umbilical aperture, there being no vessel fairly within the way of the knife in any direction. This operation has been performed during pregnancy, a complication not much affecting the case, and instances of successful results are recorded by Sir A. Cooper and Lawrence.

After the operation, under any circumstances, a large flat pad-compress must be applied over the hernial aperture, and retained in position by a broad flannel roller.

VENTRAL HERNIA signifies a protrusion through any other part of the abdominal wall, except the apertures already noticed. Commonly, this hernia occurs at the *linea alba*, the *lineæ transversæ*, or more externally, at the *lineæ semilunares*. The anatomy of ventral hernia may be inferred from the particular part of the abdominal wall where it happens to occur;

any such protrusion is usually the result of some lacerative or rupturing injury, the characters of the tumour are similar to those of umbilical hernia, and the treatment is the same.

**LUMBAR HERNIA** may be described as a variety of the preceding; but the tumour projects in the loins, between the crest of the ilium and the last rib. It arises usually from contusion or laceration of the lumbar muscles. Dr. Chapplain relates the case of a man, who after a violent squeeze between a wall and a carriage, found a tumour in his loin; and Mr. Kingdon saw a case where the bowel protruded just above the crest of the ilium at its highest point, about three inches from the spine, in the linear interval between the quadratus lumborum and abdominal muscles.

**OBTURATOR OR THYROID HERNIA.**—A very rare form of hernia in which the protrusion takes place through the obturator foramen. It was first noticed by Garengot in the early part of the last century, and has since been described by Vinson, Stanley, Hilton, Tebay, Oubr , and Bransby Cooper; and Birkett has collected twenty-five cases. The protrusion having escaped from the pelvis through the obturator canal, it is developed underneath the pectineus muscle, and in the pubic region of the thigh. The neck of the sac lies behind the horizontal ramus of the pubes, and occupies the obturator canal; the sac may then be confined between the obturator membrane and obturator externus muscle; or the protrusion makes its way, sometimes between the uppermost fibres of the obturator muscle, sometimes above them, and then the fundus and body of the sac is covered by the fascia of that muscle. The obturator vessels and nerve have a variable relation to the tumour; the artery has been found to the outer side, or to the inner side, and less frequently, behind the sac. In Stanley's case, both artery and nerve were above the sac; the former to its inner side, the latter towards its outer. The contents of the sac, are usually both intestine and omentum,—an entero-epiplocele; but only a portion of the calibre of the ileum may have descended, and be prolonged into a diverticulum of considerable length. In one case, the Fallopian tube and ovary formed the contents of the sac; in another, a portion of the urinary bladder.

*Symptoms.*—A small hernial tumour may be presented, which is more or less palpable and visible, situated below Poupart's ligament, in Scarpa's triangle and towards the pubes. There may be a slight fulness only to the eye, in the part of the thigh which is naturally hollow; but on deep pressure with the fingers, a hard lump is felt. In the female, examination per vaginam, should be made. No tumour, however, can be detected in a large majority of cases; and the existence of hernia has not been discovered during life. Strangulation has been known to supervene, without any local signs of a tumour. Acute pain in the course of the obturator nerve is the most marked symptom in all cases; pain occurring suddenly with the formation of the hernia, and proceeding from the upper and inner part of the thigh; thence extending down the inside of the limb to the knee, front of the leg, foot, and great-toe. Pressure over the site of the external aperture of the obturator canal gives rise to paroxysms of pain of great severity.

Both sexes are liable to the formation of this hernia, and females especially.

*Diagnosis.*—From *crural* hernia, a protrusion through the obturator canal may be distinguished by observing the relative positions of the

horizontal ramus of the pubes and femoral vessels. These parts, with the pectineus muscle, intervene between these two forms of hernia; in the one, they are behind the hernia and cannot be easily felt, not perhaps until it is reduced; in the other, they are in front of the tumour, which is therefore deep-seated, while the ramus and the pulsation of the artery can be felt superficially. With symptoms of strangulation and no tumour; there will still be the acute pain proceeding from the site of the obturator canal, and extending downwards along the inner side of the limb. But, exploration of the obturator region by means of an incision, will alone clear up the difficulty; and this procedure is justifiable with a view to relieving the symptoms of strangulation by operation.

Complications may be occasioned by the co-existence of one or more herniæ, especially in the inguino-femoral region. Thus, in one case, there was reducible crural hernia on either side; in three cases, a crural hernia on the same side as the obturator; in one case, on the opposite side; and in another case, an inguinal hernia on the same side as the obturator. Two obturator herniæ, one on either side, have been known to co-exist, in some cases.

The *treatment* is necessarily tentative, owing to the obscurity of diagnosis. If a hernial tumour be detected, it may be reduced by pressure so directed as to free the protrusion from the ramus of the pubes, and pass it underneath it. Otherwise, in the event of symptoms of strangulation, with, or without a hernial tumour; an exploratory operation must be resorted to. The incision should be either parallel with the trunk of the femoral artery, or with the border of the adductor longus muscle. Avoiding the femoral vein, the fascia covering the pectineus muscle and this muscle must be cautiously divided, some fat and the fascia of the obturator muscle are then reached. The tumour lies under this fascia, or possibly under the muscle, between it and the obturator membrane. The neck can be felt at the obturator canal, and the obturator nerve must be avoided.

PERINEAL HERNIA descends between the prostate gland and rectum; or between the vagina and rectum in the female,—the sex most liable. The peritoneal sac escapes between the anterior fibres of the levator ani, and is covered by the pelvic fascia. It usually contains intestine or omentum; occasionally, a portion of the urinary bladder. A tumour is presented in the perineum. Recurrence of this protrusion may be prevented by wearing a T-shaped bandage.

VAGINAL HERNIA is a variety of the preceding. The protrusion is covered only by peritoneum and the wall of the vagina; and presents a swelling in the vagina, instead of the perineum. It is easily reduced, as the orifice of the sac is usually large, and it must be retained by a sponge pessary supported by a T bandage.

PUDENDAL HERNIA descends between the ascending ramus of the ischium and the vagina. It forms a small elastic tumour in the labium pudendi, lying in the posterior and inferior half of this part, and presenting a somewhat elongated projection at the side of the vagina.

The *diagnosis* from other tumours is important. Other labial tumours which may be confounded with pudendal hernia, comprise those formed by inguinal protrusions and by collections of fluid. Of the latter, are cystic formations and hydrocele of the round ligament. These, however, are never reducible, nor diminished by pressure, and they slowly enlarge from their first appearance. From inguinal hernia, the pudendal is dis-

tinguished by its position, shape, and relations. Thus pudendal hernia has not passed through the external inguinal ring, but lies parallel with the axis of the vagina; it does not form a pyriform tumour in the labium, but a somewhat rounded mass; and it lies by the side of the ramus of the ischium, and not over the body of the pubes. From crural hernia the diagnosis consists, in the neck of the pudendal tumour being situated entirely to the inside of the ramus of the ischium and the attached muscles.

A suitable bandage is required to support the protrusion.

ISCHIATIC HERNIA escapes through the sciatic notch, above or below the pyriform muscle; usually below, between it and the spine of the ischium. Lying in close relation with the sciatic nerve and the internal iliac vessels, the tumour forms beneath the glutæus maximus muscle; but extending further out of the pelvis, it escapes below the border of that muscle and becomes sub-integumental. The hernial tumour is of variable size, soft or tense, causing more or less pain, and reducible on pressure. When not fully developed and of small size, lying also under the cushion of the glutæus muscle, the tumour will probably not be discovered during life.

When detected it may be reduced, and retained by means of a proper pad-support and bandage.

Strangulation will necessitate recourse to operation, always a difficult proceeding in regard to the anatomical relations of the hernia; and in enlarging the mouth of the sac, Sir A. Cooper recommends that the incision be made directly forwards.

DIAPHRAGMATIC HERNIA.—In this rare form of hernia, one or more of the abdominal viscera protrude upwards through an aperture in the diaphragm into the thoracic cavity. The hernial aperture may be one of the natural openings in the diaphragm; or an opening as the result of congenital defect; but usually it is an acquired aperture; caused by laceration in consequence of a violent compression or fall, or produced by a penetrating wound, as by gunshot injury. The viscera protruded are commonly the stomach or the transverse colon, with a portion of omentum. There is no peritoneal sac, and the hernia occurs only on the left side, the liver on the right side apparently preventing its formation there.

*Symptoms* arise as in other herniæ, constipation, vomiting, and pain; but dyspnœa is more or less urgent, and perhaps a hacking cough and bloody expectoration. The *diagnosis* from intussusception and internal abdominal strangulation will be scarcely possible, unless the thoracic symptoms be taken in connexion with the abdominal. Interesting cases are recorded by Dr. Reid in the Edinburgh Med. and Surg. Journal, 1840; by Dr. Copeman of Norwich in the Provincial Med. Journal of 1855, and by Mr. Erichsen in his work on Surgery.

*Treatment* will be of little avail, the hernial protrusion naturally increasing and attaining a considerable size. Mr. Guthrie, with his characteristic boldness in Surgery, proposed that an incision might be made through the abdominal wall, large enough to admit the hand to draw back the stomach into its proper place. Overlooking the doubtful question of diagnosis, it would be difficult to prevent the liability of a protrusion through the abdominal aperture after such an operation, in itself also otherwise dangerous; and it is more difficult to understand how the replaced organ could be made to remain in its place, unless indeed the opening or rent in the diaphragm were stitched up!

## CHAPTER LIV.

## INTESTINAL OBSTRUCTION.

No subject in Medicine and Surgery has a more comprehensive pathology, and the treatment of which is more frequently unsuccessful, than intestinal obstruction. Its pathology embraces numerous and diverse structural conditions of, or affecting, the intestinal canal, and in various portions of its extent; the symptoms of which in common, may be simple and obvious, but their differential diagnosis is obscure; while their course and terminations are perilous or uncertain; and the treatment having reference to such conditions, is proportionately ineffectual or impracticable.

The whole of this important but difficult subject has been ably considered by Mr. Pollock, who thus classifies these intestinal conditions. Excluding external abdominal herniæ of all kinds, the conditions, or causes, of intestinal obstruction may be divided into two classes; the acute, which generally produce most acute symptoms, early and sudden in their attack, and rapidly fatal in their results; the chronic, in which the symptoms are not at first urgent, and are more slowly developed, and recovery sometimes occurs without any assistance from treatment and often where there seems no hope of recovery.

*Acute conditions of intestinal obstruction comprise :—*

- (1) Congenital Strictures or Malformations.
- (2) Foreign bodies impacted in the intestines, and introduced through the stomach, formed in the bowel, or escaping by ulceration from the gall-bladder.
- (3) Twisting or “dislocation” of the bowel, most frequently found in the large, but often in the small intestine.
- (4) Loops, formed by bands of false membrane, adherent at both extremities; by diverticula, adherent by their apices to some portion of the viscera or abdominal wall; or by the fimbriated processes, or other portions of viscera, contracting adhesions, so as to form rings or apertures, entangling the intestine; all these usually the result of peritoneal inflammation.

(5) Mesenteric pouches; foramen of Winslow; or “thickened peritoneal sheaths,” the result of old herniæ.

(6) Invagination, often caused by worms, intestinal polypi, &c.

*Chronic conditions :—*

- (1) Constipation, habitual or accidental.
- (2) Inflamed, thickened intestine, the result of injury.
- (3) Chronic peritonitis,—tubercular and abscess.
- (4) Tumours pressing on the bowel,—hydatids, &c.
- (5) Simple stricture of intestine, the result of ulceration and other causes.

(6) Cancer of the bowel, producing contraction of the gut.

The relative frequency of different causes of obstruction irrespective of age, is shown in the following tabulated arrangement of 135 cases, collected by Mr. Hinton :—

Diseased uterus . . . . .	1	In first column . . . . .	26
Stricture of ileum . . . . .	1	Doubtful . . . . .	8
Cancer of small intestine . . . . .	2	Peritoneal adhesions, tubercles, &c. . . . .	9
Internal herniæ :		Stricture of sigmoid flexure . . . . .	10
Inguinal high up . . . . .	1	Ditto colon . . . . .	11
Diaphragmatic . . . . .	2	Ditto rectum . . . . .	11
Meso-colic . . . . .	2	Intussusception . . . . .	24
Obturator . . . . .	3	By bands, adherent diverticula, uterine appendages, &c. . . . .	36
Fæcal accumulations . . . . .	3		
Twist of sigmoid flexure . . . . .	4		
Concretions, calculi, and foreign bodies . . . . .	7		
	—		
	26		Total 135

The *order of frequency*, as to different causes of obstruction at various ages, showing the liability of different periods of life, may be thus stated; in regard to youth, middle life, and old age. In *youth*; from internal strangulation by bands of lymph, omentum, or adherent diverticula, from adhesion of coils of bowel to each other, from intussusception, from foreign bodies taken by the mouth, from cancer rarely, and hitherto found in the rectum only;—in *middle life*; from twists of large or small intestine, from gall-stones, intestinal concretions, and foreign bodies, from intussusception, from simple stricture, from mesenteric hernia, from internal strangulation by bands, &c., from peritonitis often resulting in abscess, from simple constipation, from cancer;—in *advanced life*; from cancer, from thickened intestine the result of old reducible hernia, from intussusception, from simple stricture, and lastly, from internal strangulation.

*Symptoms, and Diagnosis.*—Certain symptoms are common to intestinal obstruction arising from any cause. And, whether it be acute or chronic, these symptoms are the same, differing or rather varying only in degree. No definite line of distinction can be drawn between the symptoms in either degree; the acute subsiding into the chronic, and in this state becoming acute in their severity. Hence, the condition, or cause, of obstruction cannot be invariably inferred from the greater or less severity of the symptoms, as the ground of diagnosis. The general symptoms of intestinal obstruction are; pain in the abdomen, and localized more especially in some particular part, with abdominal distension, constipation and vomiting, followed sooner or later by collapse.

In the *acute form* of these symptoms, intussusception or invagination of the bowel, at some part of the intestinal canal, as the most common cause of obstruction, will illustrate their usual course. The upper portion of intestine slips into the lower, at the seat of invagination. The patient is struck with abdominal pain, sudden and often acute, which is referred to the seat of injury, perhaps the lower part of the belly; and he seems conscious that something has happened within the abdomen. Flatulent swelling supervenes, with much rumbling and rolling of the intestines; a commotion which can be felt and perhaps seen, and traced up to a part of the canal where it ceases. That is the seat of invagination. A constant desire to relieve the bowels is experienced, and frequent efforts are made to do so; but the constipation is obstinate, and nothing passes, or only a little wind and a lump or two of hardened fæces, or a little mucus mixed with blood, may be strained out;

not unfrequently, pure blood, fluid or clotted, is discharged. Vomiting soon sets in, at first of the contents of the stomach, and then speedily stercoraceous matter. This state continuing and increasing, the patient's anxiety and distress are aggravated. His restless endeavours to force a passage by stool, in the vain hope of obtaining relief, the accumulating abdominal distension, and pain heightening to agony; constitute a picture piteous to behold. At length prostration ensues, with some abatement of the symptoms but of a delusive character; the victim sinks exhausted in a few days, usually in about a week or ten days at the latest. Death is consequent on the exhaustion, coupled with gangrene and peritonitis.

In *chronic* obstruction, stricture of the bowel, and commonly of some portion of the large intestine, as of the sigmoid flexure or of the rectum, is attended with similar symptoms; but they are less speedily developed and less marked. Progressing inability to relieve the bowels, and narrow constricted, or flattened motions dwindling down at length to constipation, with nausea and then vomiting less early stercoraceous; are succeeded by tympanitic distension and pain. Death may not occur for weeks or months, recovery takes place when least expected.

The *diagnosis* as to the particular *cause* of obstruction cannot be positively determined by any known special symptoms, except perhaps where the seat of obstruction is low down near, or in the rectum. Nor, with regard to more internal obstructions, is the structural condition so important practically, as its particular *seat*,—the portion of intestinal canal affected. To discover this point, a most careful and thorough examination of the abdomen should be made externally; and an exploration internally as far as possible, through the passages,—the rectum, and the vagina in the case of a female patient.

The diagnostic symptoms in the principal different conditions, acute and chronic, may be thus stated. In *intussusception*, the chief signs are; the fixed pain and the distension, with tenesmus and bloody mucous stools, probably also the detection of an intumescent tumour, and the early age of the patient. In *volvulus* or *twisting* of the bowel, the abdominal distension may be very unsymmetrical; great tympanitis on one side, and flattening on the other, with the symptoms of internal strangulation. In *internal hernia*, the suddenness and marked severity of the symptoms, are somewhat distinctive. In *chronic stricture*, the converse character, and the order, of the symptoms as just described.

Examination per rectum can be made with the finger or by means of a bougie or injection. When the stricture is situated low down, it may be reached with the finger, and a more satisfactory exploration made as to the nature and extent of the constriction. *Simple* stricture is limited usually to a circular band, having a sharp margin around the aperture which communicates with the intestine above. *Cancerous* stricture extends along the rectum, and presents considerable thickening and an irregular or nodulated surface. If a bougie be introduced, it must be passed up with great caution and no degree of force, as frightful damage might, and has been done by misadventure. An injection of warm water may be immediately returned or only partially retained, thus plainly declaring the presence of a stricture; especially if the return current should wash away with it any feculent matter, lodged below the obstruction.

*Treatment*.—The general indication of treatment in intestinal obstruction—from whatever cause arising—is plain enough; namely, to restore the continuity, and the normal action of the bowel. But how to ac-

comply with this object, is always a question of difficulty? Its rational fulfilment would first imply, the previous detection of the causative condition in operation,—as to its nature and seat. This precision of diagnosis cannot, as we have seen, generally be attained. So we must be guided by more general rules of treatment. Too often these are ineffectual or impracticable.

*Medicinal* measures have regard to restoring the normal action of the bowel, and allaying the excruciating pain and inflammation, more particularly incident to acute obstruction. An absolutely negative rule is never to administer purgatives; *i.e.*, medicines by the mouth, to force evacuation through the obstructed portion of the intestinal canal. Enemata may generally be used with advantage, oft repeated and copiously, especially if the obstruction is apparently the result of constipation. Mild enemata are most serviceable, as simply of warm water; their mechanical action being more effectual than any specifically aperient action. The injection of air or inflation, by means of the stomach-pump, has occasionally proved effectual in overcoming the obstruction, and thus restoring the natural action of the bowel. As the intestinal canal becomes inflated, something is felt to give way suddenly, and a motion soon follows. This practice has been most successful in apparent intussusception, and as occurring in infants and children. Opium is the most efficacious agent for the relief of pain, and it exercises some remedial influence on peritoneal inflammation. But with symptoms of peritonitis, calomel may be combined with opium, and leeches, followed by hot fomentations should be applied to the abdomen. Solid food, of any kind or in the smallest quantity, must be rigorously prohibited, the patient should be supported entirely by the imbibition of fluid nourishment; and this injunction is scarcely less applicable if the obstruction has yielded, and the bowel lies as yet disorganized or functionally paralysed.

When medicinal treatment has failed, the question of *operative* interference arises. It is a dire resource, almost as perilous as the condition sought to be removed. Yet it is justifiable as affording the only chance of saving life, in a state otherwise inevitably fatal. The period of obstruction when such surgical intervention becomes warrantable, cannot be determined absolutely. As a general rule, that laid down by Phillips, should be observed; recourse to operation after three or four days have passed, without any relief from ordinary means, constipation being complete and stercoraceous vomiting persistent. Constipation alone will not justify operative interference, unless the obstruction be complete; but with vomiting as a symptom of internal strangulation, an operation is the only alternative between probable life and certain death. Intussusception may be taken as an exception, owing to the pathological condition of the invaginated portion of intestine, the resultant sloughing and separation of that portion of the bowel. Moreover, the following self-curative results are interesting:—in 24 cases of intussusception, occurring at various periods of life, from two months and a half to fifty years of age; 13 of the patients died unrelieved, some as early as three days, some as late as forty days, from the commencement of the symptoms. But in the other 11 cases, the invaginated pieces of intestine sloughed and were passed by stool. Of these cases, only 2 died soon after the passage of the slough; the remaining 9 entirely recovered. The patients who recovered were ill for periods varying from five to thirty days, and their ages ranged from six to fifty years.

An operation for the relief of intestinal obstruction will vary in its situation and design according to the seat and nature of the obstruction.

In respect to the *small* intestine, the abdominal wall, and thence the peritoneum, must necessarily be opened, in order to reach the seat of obstruction. Thus may be relieved; obstruction of a hernial character, whether depending on a constricting band, or the gripe of a fissure in the omentum or mesentery through which a coil of intestine has slipped; or a volvulus of the bowel may be untwisted. Least successful will be the operation in the following conditions; when peritonitis has supervened from prolonged strangulation; in the obstruction from foreign bodies or calculi lodged in the bowel; and in stricture of any portion of the small intestine.

*Gastrotomy or the Abdominal Section* may be performed in the following manner. The arrangements resemble those of ovariectomy in the female. The temperature of the apartment should be raised to about 70° Fah., and flannels wrung out of warm water be at hand to protect the bowels; the bladder emptied, and chloroform administered. Then, the Surgeon, standing conveniently between the legs of the patient recumbent, makes an incision, usually in the middle line below the umbilicus; or elsewhere, over the seat of obstruction, when that can be diagnosed by an intumescent tumour. Proceeding cautiously towards the peritoneum, this membrane is carefully slit up by a probe-pointed bistoury guarded by the fore-finger beneath. Any protruding coils of inflated intestine are then to be gently drawn aside by an assistant using the wet flannels, while the operator searches carefully upwards along the empty coils of the bowel until he arrives at the source of obstruction. A constricting band may then be divided cautiously with the scalpel or broken through with the finger; a portion of intestine may be withdrawn from a fissure in the omentum or mesentery, or a twisted portion of bowel may be untwisted. In the event of not thus releasing the bowel in any case; as a last resource, it might be opened as low down as possible, and the aperture stitched to the integument of the abdominal wound, with the hope of establishing an artificial anus. Otherwise, under ordinary circumstances, the bowels should be returned, and the abdominal incision closed by the interrupted suture, supported by a compress and bandage. After-treatment must be conducted on the general principles relating to abdominal wound with peritonitis.

Obstruction of the *large* intestine may be treated by operation, through the abdominal wall, in either iliac region; or in either lumbar region.

The design of any such operative procedure is, however, not to overcome the obstruction, commonly a stricture in some portion of the large intestine; but to relieve constipation by forming an artificial anus. Of course, therefore, the bowel must be opened and above the seat of stricture. Hence, stricture of the rectum or of the sigmoid flexure of the colon, will necessitate an opening of the *descending* colon; or in the former case, the *sigmoid flexure* might be opened; and stricture of the descending or of the transverse colon, will require a transference of the operation to the *ascending* colon, or to the *cæcum*.

These four sites of operation have, however, different advantages; not as to their respective eligibility for access to the bowel operated on, but with regard to not implicating the peritoneum. In both the operations pertaining to the sigmoid flexure and the cæcum; an opening is made in the iliac region, left or right, whereby in either case, the peritoneum must

be wounded; whereas, in both the operations on the colon, or by colotomy as it is termed, the bowel is reached in the lumbar region, left or right, and the peritoneum may be avoided.

The *iliac* operation was first suggested by Littre in 1710, who recommended that the sigmoid flexure of the colon might be opened from the left iliac region; but Pillore, a Surgeon of Rouen, first performed the corresponding operation in 1776, by opening the cæcum from the right iliac region. Both these were cases of stricture of the rectum. It may here be added that, the *transverse* colon has been opened, in one case, for stricture of the rectum; an operation performed by Fine of Geneva, in 1797.

The *lumbar* operation was proposed by Callisen, in 1796; and he performed it on the descending colon, in the left lumbar region; the subject being the dead body of a child. In seeking the intestine, he accidentally missed the cellular interval uncovered by peritoneum, and wounded this membrane. The operation was thenceforward deemed impracticable, and not attempted on the living body. Amussat revived it in 1839, and extended this procedure to the ascending colon, in the right lumbar region; modifying also the line of incision from a vertical incision, which Callisen had recommended, to a transverse one. Certain advantages are thus gained; it makes the operation easier and more certain, and avoids the danger of dividing the lumbar vessels and nerves; it facilitates finding and opening the intestine between the duplicature of peritoneum, without wounding the serous membrane; and it enables the operator to establish the artificial anus more anteriorly.

*Colotomy or Amussat's operation.*—The guide to the incision, is the interval between the crest of the ilium,—its middle third, and the last false rib, and external to the outer margin of the erector spinæ muscle. Commencing just in front of the last-named boundary, an incision is carried forwards transversely, corresponding to the middle third of the iliac crest, and to the extent of from four to six inches. The muscular layers of the abdominal wall are then successively divided, and perhaps the external border of the quadratus lumborum muscle. Clearing away the areolo-adipose tissue, which is sometimes membranous and semi-transparent resembling peritoneum; the colon presents itself, and the more so if loaded; it appears at the bottom of the wound, and free of peritoneum. It is recognised by its muscular character, somewhat greenish colour, and distended sacculated appearance; and the more fully the gut is engorged, the more freely will it have uncovered itself through the duplicature of the peritoneum—the meso-colon. The gut should be hooked up with a tenaculum, avoiding the peritoneum on either side, and drawn well out to the surface of the wound; in order to prevent any feculent effusion into the cellular texture, as the gut gradually collapses by discharging its contents when opened. An aperture is then made with a bistoury, and there usually takes place a gush and copious flow of feculent fluid. Basins should be at hand to receive the abundant evacuation. The margin of the opening in the colon is then secured to the integumental incision, by means of a few points of suture; so that an artificial anus thus formed may become established permanently. After-treatment consists, in combating collapse and peritonitis. Opium and support are the principal constitutional requirements; and scrupulous cleanliness is the most urgent local observance to be attended to. The constant discharge of fæces through the wound may generally be controlled by the use of an ivory ball, fitting the aperture in the bowel, and attached to a small shield, over

which a soft thick piece of india-rubber should be fastened; the whole contrivance being retained in position by a bandage.

This operation has now been resorted to about fifty times. Its results may be gathered from the analysis of 44 cases, in which an artificial anus has been formed by opening the large intestine. From a paper by Mr. Cæsar Hawkins, published in the *Medico-Chirurgical Transactions*, vol. xxv.; it appears that of these 44 cases, in 17 the anal opening was made through the peritoneum, and in 26 behind that membrane; but as 5 of the peritoneal sections were exceptional cases, 12 only are left to compare with 26 cases of operation behind the peritoneum. Of the former, 7 died and 5 recovered,—the recoveries amounting, therefore, to only 41 per cent.; whereas, of the 26 cases of unopened peritoneum, 10 died and 16 recovered,—the proportion of recoveries amounting to 61 per cent. In all these cases, the large intestine was the seat of operation: it was performed on the *right* side in 10 instances; in 4, the right colon and cæcum were opened through the peritoneum, and all of these cases were fatal; whilst of the remaining 6, in which the right colon was opened *behind* the peritoneum, 4 recovered. The advantage, therefore, on the right side, is in favour of the lumbar, or Amussat's operation. On the *left* side, however, the results are less favourable. Of 8 cases in which the left colon was opened through the peritoneum, 5 recovered and 3 died; whilst of 20 cases in which the *lumbar* operation was performed, 11 recovered, but 9 were fatal.

Respecting then any operation for the formation of artificial anus in intestinal obstruction, affecting the large intestine; these results well deserve serious consideration.

## CHAPTER LV.

### PARACENTESIS ABDOMINIS.

IN dropsy of the abdomen; whether ascites or ovarian, the peritoneal sac, or an ovarian cyst becomes distended with fluid; and either cavity may be emptied of its contents by *Tapping*.

This is a very simple operation. The bladder having been emptied, the patient should be seated on the edge of a chair, or, if very weak, turned sideways to the edge of the bed; so that in either position the protuberant belly shall be exposed. A flannel roller, or a jack-towel, the breadth of the abdomen from above downwards, is then passed round, and the ends crossing behind the loins, are given in charge of an assistant on either side. They should draw the roller equably, to compress the abdomen uniformly, as the water flows. A small aperture is cut in the roller, corresponding to the point where the abdominal puncture is about to be made; namely, in the middle line, about two or three inches below the umbilicus. The Surgeon seating himself before the patient, as placed in the sitting posture; he makes a small vertical incision at the spot indicated, and through the integumental wound thus made, a large-sized trocar and canula is thrust into the abdomen. (Fig. 424.) Or the thrust may be made at once, without any preparatory incision, the skin yielding without any appreciable damage to this texture. On with-

drawing the trocar, taking care that the canula do not slip out after it, the fluid spouts out in a full stream, and is received into a pail below. A convenient and more elegant arrangement, is the adaptation to the canula, of a tube of india-rubber, provided with a stop-cock. The kind of fluid varies in colour and thickness; in ovarian dropsy, it is commonly of a brownish coffee-colour, turbid, and thick or of almost glutinous con-

FIG. 424.

sistence between the thumb and finger, and it froths up as the stream continues. The assistants should draw the roller firmly, and especially as the stream weakens and dribbles, when air might pass back into the peritoneal cavity. Towards the last, the fluid may be tinged with blood, owing apparently to the mouth of the canula impinging on the visceral layer of peritoneum. Then, unless by further traction, the stream can be resumed, the canula should be withdrawn.

The patient may become faint, as the fluid-pressure on the abdominal vessels diminishes; when a little brandy-and-water or wine may be administered, and the orifice of the canula stopped with the finger for a while. Sometimes the fluid suddenly ceases to flow, a bit of intestine coming in contact with the end of the canula, or the tube being blocked up; in either case, the obstruction may be removed by introducing a piece of bougie or other blunt-pointed tube.

On withdrawing the canula, a small strip of adhesive plaster will suffice to close the abdominal aperture. A broad bandage should, however, be well applied round the abdomen to maintain compression; thus preventing faintness, and possibly the reaccumulation of fluid or recurrence of dropsy.

This operation may be modified according to circumstances; any other convenient situation may be chosen for the puncture, provided that there be no tympanic resonance to indicate the presence of intestine, but the dulness on percussion of a fluid collection; and the course of the epigastric vessels must also be avoided. The intestine,—a portion of jejunum, has been wounded, and yet the patient recovered. This accident occurred in a case communicated by Mr. Gay, to the Pathological Society, and which is recorded in the second volume of the Society's Transactions.

## CHAPTER LVI.

## DISEASES, INJURIES AND MALFORMATIONS OF THE RECTUM, AND ANUS.

DISEASES of the Rectum and Anus pertain to the terminal portion of the large intestine, in its limited course of six or eight inches from the left sacro-iliac articulation to the anal orifice in the perineum.

Surgically considered, the rectum might almost be said to have a more limited extent,—in regard to its liability to disease. At its commencement, the bowel inclines downwards and inwards to the middle of the sacrum; thence it curves forwards in front of this bone and the coccyx,—behind the bladder, vesiculæ seminales, and prostate, in the male, or the cervix uteri and vagina, in the female; and opposite the tip of the coccyx, or the prostate anteriorly, it inclines downwards and backwards to the anus,—leaving an interval between this portion of the bowel and the membranous part of the urethra and its bulb. It is in these two latter portions of the gut, or in about the lower half of its whole extent, that most rectal affections are congregated; and they derive some additional importance from the relative position of the bladder and prostate gland.

Diseases thus crowded together, may be most conveniently arranged according to their pathological association and diagnosis, observing also their order of frequency in the practice of this branch of Surgery. Affections of the rectal tube and of its anal aperture will, therefore, be considered as follows:—Inflammation and Rectal Abscess; Fistula in Ano; Ulcer of the Rectum, and Fissure of the Anus; Hæmorrhoids—external, internal, and Prolapsus of the Rectum; Polypus of the Rectum; Stricture of the Rectum—Simple, Cancerous; Rectal Fistula,—Vesical, Vaginal; Anal Tumours; Anal Contraction; Injuries; Foreign bodies; Congenital Malformations; Functional Disorders.

INFLAMMATION AND RECTAL ABSCESS.—In the loose cellular texture around the rectum, and particularly in that of the ischio-rectal fossa on either side of the anus, inflammation is very apt to occur, and speedily pass into suppuration. According to the situation of the abscess thus formed, it is more or less deep-seated or superficial; but in either case, the matter has a tendency to burrow upwards in the direction of least restraint,—the pelvic cellular tissue leading from the ischio-rectal fossa, beneath the levator ani muscle, rather than towards the thick and unyielding integument continued from the buttock over the fossa.

The *symptoms* of rectal abscess are, not unfrequently, indistinct. Pain is felt in the fundament, more especially on passing a motion, and if the *faeces* be hard and irritating. The pain has the usual throbbing character when matter forms; though sometimes this takes place without scarcely any sensation, but that of a dull aching weight as matter accumulates. Hence, two varieties of abscess may be recognised,—the *acute* and the *chronic*. In both, there will be some tenderness on pressure, on one side of the anus; swelling also sooner or later becomes apparent, which is hard and brawny though perhaps softer at one point. In connexion with these local signs, other symptoms may be present; a constant bearing down and desire to relieve the bowel, yet with straining efforts, only a little mucus passes; or there may be obstruction to the evacuation of

æcæ, and constipation; while a troublesome irritability of the urinary bladder and frequent micturition is experienced, or a difficulty in passing water and even retention of urine. The situation of *pointing* is various, and specially important. Rectal abscess coming to the surface, points slowly in the perineum by the side of the anus; occasionally, however, at some distance from the bowel,—in the middle of the thigh, or backwards, near the trochanter; but, not unfrequently, it opens into the bowel, and perhaps also externally in the perineum. Fistula in ano results when any opening of a rectal abscess becomes established in the neighbourhood of the anus; and the varieties of fistula thus formed will be noticed presently. The matter discharged from an abscess adjoining the rectum has always a fæcal odour; more perceptible if there be a communication with the bowel, although it is distinctly fæcal in any case, owing probably to transudation.

*Causes.*—Various local causes give rise to this abscess; any source of irritation,—as habitual rectal constipation, or a foreign body in the bowel, as a fish-bone which Liston found, the core of an apple which Brodie detected, or a piece of tooth; occasionally, caries of an adjacent bone, as of the coccyx or sacrum, or of the tuberosity of the ischium in one of my own cases; or disease of the bowel itself may be the cause in operation; lastly, some external injury, as a kick or contusion, may have induced inflammation; or exposure to cold, as by sitting on a cold stone, have brought about congestion followed by suppuration. Chronic rectal abscess not unfrequently results from obstruction to the venous circulation, and is symptomatic of some organic disease of the lungs, liver, or heart. Often, as chronic abscess co-existing with a phthisical tendency or actual phthisis, the local disease is of constitutional origin. Whenever dependent on venous obstruction, congestion of the hæmorrhoidal veins, or piles, is commonly associated.

*Treatment.*—In an early stage, before suppuration has occurred, resolution can sometimes be effected. Laxative aperients rather than purgatives, and careful regulation of the diet, with warm fomentations, may succeed in dispersing the inflammation. If not thus serviceable, these measures will prepare the way for the better management of suppuration. An early opening should be made to prevent the matter burrowing around the gut. As soon, therefore, as the formation of matter can be detected or suspected, although fluctuation be very indistinct, and certainly before any pointing has appeared; a sharp-pointed bistoury should be entered carefully by the side of the bowel, and if a drop of pus rises up by the side of the blade, the opening must be sufficiently enlarged downwards to let out the matter already accumulated and allow a free discharge subsequently. A strip of lint is then inserted. The abscess may heal from the bottom, without communicating with the bowel or leaving an external fistula.

**FISTULA IN ANO.**—Any pus-secreting tract which passes up by the side of the anus, is designated, from its proximity, a fistula in ano. It results from the contraction and partial closure of an ischio-rectal abscess, leaving only this narrow channel. Commonly, it opens both internally, into the bowel, and externally in the vicinity of the anus; sometimes, there is but one orifice,—an external, or an internal. Corresponding conditions of fistula may, therefore, be recognised.

*Complete* fistula has two openings; one into the bowel, another on the surface of the skin. *Incomplete* or blind fistula has but one opening; an

external opening on the skin, but no communication with the bowel,—constituting *blind external* fistula; or there may be an internal opening into the bowel, but no opening on the skin,—constituting *blind internal* fistula.

These fistulous openings have some features worthy of notice. The *integumental* orifice is situated usually over the fossa by the side of the anus; but it may be removed to some distance outwards and posteriorly at the back of the buttock, and towards the great trochanter. In point of size, the orifice is smaller or larger, admitting only a probe or a director easily; it has a puffed everted appearance, with perhaps protuberant granulations indisposed to close, and moist with a constantly oozing, fetid, purulent discharge. Sometimes, there is more than one fistulous opening, even several, resembling a water-pot spout, and all discharging matter. These orifices are scattered in various directions contiguous to the anus; and lead by very tortuous, devious, routes to the abscess, and thence to the bowel; branch sinuses, perhaps, passing off from these fistulous tracts. On either side of the gut, also, one or more fistulous openings may have formed. The *rectal* orifice varies chiefly in its height up the bowel. Commonly, it is situated just above the sphincter ani, where the rectum enlarges, especially in old people and females; this opening is, however, not the termination of the fistula, which usually runs up further outside the bowel into a cul-de-sac. It has been affirmed by some of the best authorities, that the inner orifice of fistula in ano is never higher up in the bowel than about the spot referred to. Mr. Ribes in 1820, and previously, I believe, Sabatier held this opinion; it was supported by Sir B. Brodie and Mr. Syme, and the special observations of Dr. Bushe of New York tend to the same conclusion. On the other hand, Mr. Curling disproves this conclusion, and although Mr. Quain does not take up the question in his clinical lectures on Diseases of the Rectum, yet the facts there stated are equally opposed. In Case 29 of these lectures, the inner opening was situated more than two inches up the rectum, and equally high up in Case 32. I may add, that in a case of complete fistula, on which I operated, the inner orifice was three inches from the anus.

The *diagnosis* of the three conditions of fistula in ano, is very obvious. Complete, and blind external fistula, both present an external opening by the side of the anus, or otherwise placed. But on passing up a probe or director along the course of the fistula to the bowel, the fore-finger of the other hand having been introduced into the gut to feel for the point of the instrument; in the one condition of fistula, an opening is discovered through which the probe can be made to touch the finger,—no septum intervening; in the other condition, the point of the probe may be felt more or less plainly through the thickness of the bowel, but not in contact with the finger,—a membranous septum, however thin, always intervening. Blind internal fistula is less readily detected. There may be some brawny swelling and tenderness on pressure externally, but no opening; a purulent discharge occasionally from the interior of the bowel, and the escape of pus on pressure over the ischio-rectal fossa, will both lead to the diagnosis of an internal fistula; and this will be confirmed by feeling the orifice in the gut, when the finger is passed into the anus.

The relation of fistula in ano to rectal abscess has been disputed. Abscess is said to occur first, external, to the bowel; then opening into it, and, outwards by the side of the anus, a complete fistula is thus constituted. If the abscess opens only externally, a blind external fistula

results. This mode of fistula formation I have already alluded to, and it is that which Mr. Syme maintains. Conversely, ulceration of the mucous membrane of the bowel is a reputed mode of origin; and leading to the formation of an opening, and an abscess externally,—a blind internal fistula is thus constituted, which may result in complete fistula. This was the opinion held by Sir B. Brodie. In the one mode of formation, abscess precedes and causes, in the other, it follows and results from,—the formation of an opening in the gut. Doubtless, fistula originates in both ways. Blind external fistula—not an uncommon condition—must necessarily arise by an abscess independent of the rectum, there being no communication with the bowel. The particular way in which fistula arises, is determined probably, by the causes of rectal abscess. Any occasion of irritation or of venous congestion, external to the bowel, will probably produce abscess in that situation, followed by fistula; any impaction of feces or a foreign body in the rectum, will probably produce ulceration of the mucous membrane, followed by some amount of feculent extravasation into the surrounding cellular texture, and abscess as the result of this irritation.

The *prognosis* is unfavourable in proportion to the organic or constitutional origin of the disease; as in fistula arising from venous congestion, and dependent on some organic disease of the heart, liver, or lungs,—especially phthisis.

*Treatment.*—An *operation* is usually the only means of cure. Such interference is contra-indicated, whenever fistula depends on some persistent cause. Operation would then be either useless or prejudicial,—it would fail to cure the disease, or, being thus successful, it would develop the causative condition into greater activity. Therefore, operative interference, for the cure of fistula, should not be had recourse to,—in fistula connected with any persistent local condition, as disease of the rectum, or caries of the sacrum or coccyx; and still less, when it is dependent on some constitutional condition, advanced phthisis in particular. In this disease, the drain by constant discharge from the fistula might seem to aid in reducing the general health; but its derivative influence on the pulmonary disease is a more important consideration.

No principle of treatment is more simple than that of the established operation for fistula in ano; and no operative procedure is generally more easily performed, or is more effectual. The principle is simply this,—that the fistula being kept open by the almost constant action of the adjoining sphincter ani muscle, division of this muscle will set the part at rest, and allow it to heal and close from the bottom. Accordingly, the bowels having been well cleared with castor oil or other mild aperient medicine, and the rectum emptied by an enema on the day of operation; the patient is laid on the side most convenient to the operator, the thighs are drawn up so that the buttocks shall project over the side of the bed or table, and the latter held apart by an assistant. A probe, or director, introduced through the external opening in the skin, will guide to the internal opening, should it exist, or to a spot where the bowel is thin and about to give way. At the same time, the fore-finger of the other hand is introduced into the rectum until it rests upon or feels the point of the director. A curved, narrow-bladed bistoury, blunt-pointed or sharp-pointed, according as the fistula is complete or incomplete, is then slid through the external orifice of the fistula, along the groove of the director, until it touches the point of the finger in the rectum (Fig. 425); when

the fistulous tract is laid open freely into the bowel—the knife dividing at one sweep, the skin, sphincter and bowel, and coming out of the anal aperture, with its point still resting on, and protected by, the point of the finger. It will be observed, that the cul-de-sac, above the opening of the bowel, is left undivided in the operation as thus described. Its division is

FIG. 425.

unnecessary, to fulfil the principle of the operation, and might implicate branches of the middle hæmorrhoidal artery, producing serious hæmorrhage. This terminal portion of the fistula generally closes, with the open tract, now that the sphincter ani is divided and set at rest. If one or more branch sinuses exist, they also must be laid open.

Complete fistula, and blind external fistula, are thus operated on. Blind internal fistula presents no external orifice; a bent probe must, therefore, be passed up through the anus, and diverted into the rectal opening, thence downwards to the integument. When its point is plainly felt projecting, a puncture should be made with a sharp-pointed bistoury and the operation completed in the usual manner.

In performing the operation for fistula in ano, with the ordinary bistoury, two accidents are liable to occur, as contingent on the construction of the instrument—an unprotected knife. Its *sharp* edge—so keen, as Pott observes—may pass out of the fistulous tract; or the point, necessarily *sharp*, in the absence of an inner opening, may pass out, instead of penetrating the bowel. Both these accidents are liable to happen in the act of sliding the knife through the fistula; particularly if the tract be long, narrow, and tortuous; while misdirection of the point may occur, more especially in blind external fistula. Moreover, there is the embarrassment caused by the additional thickness of the director in the fistulous tract, whenever this instrument is also indispensable—*i.e.*, in precisely the above-named conditions. To obviate any risk of either of these two misadventures, and of the mechanical embarrassment; I, some years ago, invented a knife, which has an ensheathed blade, and is hence denominated the “concealed fistula-knife.” It has the appearance of an ordinary director, set in the handle of a scalpel. This director is introduced through the fistula into the bowel, when by depressing a button on the back of the handle, the instrument is *then* converted into a knife, having a sharp point, which can be passed through the bowel, if the fistula be incomplete;

and the operation finished in the ordinary manner. One instrument, therefore, suffices to begin and complete the operation, and by a more simple, speedy, and safe procedure. I have operated with this concealed knife many times, and under circumstances of some difficulty; always with ease, and with an in-and-out-again movement, not otherwise safely practicable.

In concluding the operation, a narrow strip of oiled lint should be passed up the bowel, into the cul-de-sac when it exists, and laid within the wound of the open fistulous tract. Thus healing and closure by granulation, may take place from the bottom. But it will be unnecessary and undesirable to continue this lint-tent longer than the first two or three days. If its application be unduly prolonged, the wound may become a chronic granular cleft, indisposed to contract and cicatrize; or it heals, leaving a gap, and a weakened state of the sphincter muscle with a tendency to the involuntary escape of *fæces* and *flatus*. This latter state I have known to remain for five or six years after the operation; and it is usually unavoidable to some extent in the after-management of an operation, when the fistula itself was extensive, chronic, or both. The discomfort and misery entailed by the perpetual liability to feculent discharge, may be almost worse than the original fistula; usually, however, the sphincter gradually regains its strength and the power of retention is restored. But I know of no operative resource for substituting an efficient contraction of the anal aperture.

*After-treatment.*—The bowels having been thoroughly emptied before operation, no action may take place for two or three days; any liability to disturbance must be restrained by opium, and then the gentlest aperient—castor-oil, should be administered. Hæmorrhage rarely proves troublesome. At the time of operation occasionally, bleeding may be such as evidently to require special means to arrest it; the wound should be plugged with lint to the bottom, and a compress applied, secured by a T bandage. Then, the patient should be watched, lest hæmorrhage continuing internally and the blood passing up the bowel, a large quantity might be lost imperceptibly. Secondary hæmorrhage, occurring in the course of a few hours, must be treated in like manner; the clots removed, ice-cold water injected, and a plug introduced well up the bowel. The wound heals usually in two or three weeks. If sluggish and indisposed to close, the healing process seems to be assisted by the administration of the *confectio piperis nigri*, in drachm doses, at bed-time.

*Ligature* of the septal portion of bowel, has sometimes proved successful. This operation has of late years been strongly advocated by Mr. Luke. A horsehair, or flexible wire ligature is passed, by means of an eyed-probe, through the fistula into the bowel; the two ends are tied, and adapted to a small screw. The ligature is tightened, as it ulcerates its way through the septum; in a week or two it becomes detached, the fissure at the same time granulating from the bottom. One advantage attends this method of dividing the fistula, hæmorrhage is less likely to occur. Ligature may, therefore, be more appropriate than cutting with the knife, in deep fistula; where that operation might implicate the middle hæmorrhoidal artery. But, in long, narrow, and tortuous fistula, the introduction of a ligature will scarcely be practicable; and in any case, this method of cure is tedious and painful.

*Stimulant application* to the fistulous tract, is also an occasional mode of cure, by inducing contraction and closure. This, however, is limited

to blind external fistula, of short extent, and free from induration. Such application may be made, either by means of irritant injections, as tincture of cantharides or tincture of iodine, used daily; or by passing up a probe armed with fused nitrate of silver. In the course of this treatment, the general health must also be improved by medicinal and hygienic measures.

*Double* fistula in ano requires a double operation, if the fistula be complete on both sides; and both may be advantageously slit up at the same time. Double *sinuses* with only one internal orifice, must both be laid open; but the operation should be completed only on the side where the inner orifice exists, leaving the bowel untouched on the other side.

ULCER OF THE RECTUM, AND FISSURE OF THE ANUS.—These two conditions may exist separately, or co-exist. *Ulcer* of the rectum is situated just within the sphincter ani, and usually posteriorly. Extending outwards, perhaps, to the anal aperture, it is commonly associated with a small external hæmorrhoid or pile, beneath the base of which the terminal limit of the ulcer lies concealed. Thus extended, the ulcer is situated partly within the rectum, just above the ring of the sphincter muscle; and partly within the circumference of the anal aperture, approaching the condition of fissured anus. The ulcer varies in size, from a large pin's head to a large split pea; and when distended has an ovoid or circular shape; its surface is smooth, or rough when relaxed, and the colour may be reddish or sloughy-ash grey. Two ulcers are sometimes found.

*Fissure* of the anus is situated at the anal aperture—the junction of the mucous membrane and integument; and not involving the rectum. It consists of a crack or streak of excoriation, somewhat indurated, and placed between the loose folds of mucous membrane and integument which surround the anus. An overhanging pile is commonly associated with fissure. Two or more such fissures also not unfrequently occur.

The *Symptoms* of these ulcerative affections are easily recognised. Both states are acutely painful, out of all proportion to the limited extent of structural lesion, and as it continues, the constantly recurring suffering gives a remarkably haggard and pallid expression of countenance; both states also, especially rectal ulcer, are attended with more or less spasmodic contraction of the sphincter, and with some irritability of the urinary bladder, a tendency to spasmodic stricture and seminal emissions. *Spasm* of the sphincter has been regarded as a peculiar and independent affection—such is the opinion of Copeland and Syme; it is more probably, as Mr. Quain alleges—secondary and sympathetic.

Proceeding to *diagnosis*:—with ulcer of the rectum, sometimes distinguished as “painful” and “irritable” ulcer, there is most acute burning pain in passing a motion; the suffering increases after the act, and continues for a considerable period, varying from a quarter of an hour to several hours and then subsiding into ease until the bowels are again moved. With fissure of the anus, there is smarting or even equal pain, as a motion passes; but it subsides within a few minutes, when the temporary irritation has ceased, and the more readily if the part be sponged and cleansed properly after the act. Then again, some amount of bloody-purulent discharge may be observed in both ulcerative affections; but in that of the rectum, there is no external appearance of ulceration, unless the part be protruded and carefully examined; yet the ulcer can be felt and seen. On introducing the finger just *within* the anus, and generally

towards the coccyx, a small depressed surface can be detected; touching this spot causes sharp, burning pain, and provokes a more powerful spasmodic contraction of the sphincter around the end of the finger. By examining the rectum with the speculum ani (Fig. 426) the ulcer may be brought into view through the open side of the tube. To facilitate either method of examination, in this, and all other painful affections of the interior of the rectum, the influence of chloroform is an invaluable boon both to the patient and the Surgeon. In fissure of the anus, the ulcer-crack can be discovered by a little careful search *externally*.

Fig. 426.

The *causes* of these ulcerative affections would seem to be; rectal constipation, in the production of ulcer within the bowel, and this may be aided by violent straining defæcation; while the external fissure is probably induced by want of cleanliness, as by gonorrhœal matter coming in contact with the thin sensitive skin around the anus, or by that syphilitic discharge which begets mucous tubercles. Females, therefore, are most liable to such anal ulceration; owing to the proximity of the vaginal discharge, and the easily-cracking nature of their perineal and anal integument. A sedentary occupation predisposes to fissure.

*Treatment.*—In *recent* ulceration and of *slight extent*, a cure may sometimes be effected by stimulant applications, with anodyne suppositories to allay pain; the bowels being well regulated by castor-oil, or other gentle aperient, and scrupulous attention to cleanliness observed after any action of the bowels, or as to any other source of irritation. Accordingly, the ulcerated spot may be touched occasionally with stick-nitrate of silver or a piece of sulphate of copper; and in fissured anus, the caustic must be run along within the crack so as to fairly touch the bottom of the angle. A weak lotion of sulphate of copper, or zinc, acetate of lead, or the black mercurial wash, may also be sponged up, two or three times a day. An anodyne and astringent suppository is highly recommended by Mr. Erichsen, as very efficacious in this and many other painful affections of the anus. It consists of 2 grains of extract of belladonna, 2 grains of the acetate of lead, and 4 of tannin, made up to a proper consistence with a little suet. This may be introduced into the rectum every night and allowed to dissolve there. I have found nothing so soothing, and apparently protective to the ulcer, as a suppository of simply pil. sapon. co, grs. x. The beneficial effect of these topical applications is estimated by the mitigation of pain, and by the ulcerated surface assuming a healthy reddish granulating appearance, and contracting.

In *old-standing* and more *extensive* ulceration, operative interference is the only cure. The old procedure, originated by Boyer, was division of the sphincter ani, so as to set this muscle at rest, as by the operation for fistula in ano. Copeland proved that this deep cut is quite unnecessary; and that the more superficial incision, limited only to the mucous membrane, through the whole length of the sore, is equally curative. This section of the mucous membrane alone, has since been advocated by Brodie, Syme, and Quain; and it is now the established operation for the

cure of ulcer of the rectum and fissure of the anus. The superficial muscular fibres of the sphincter must, however, necessarily be cut, when the ulcer has destroyed the whole thickness of the mucous membrane. Mr. Curling once noticed the fibres of the sphincter at the base of the sore, in which case they would be divided by any incision through the sore.

The operation is easily done, when the anus is thoroughly opened by an assistant. The fore-finger is introduced into the rectum, opposite the sore, and a probe-pointed bistoury slipped up sideways, and planted just above the ulcer or fissure; the blade is then drawn downwards and outwards steadily along the centre of the sore or in the fissure, dividing the mucous membrane—the depth being about the eighth of an inch. It may be advisable that a thin strip of oiled lint should be laid in the wound and retained for a day or two.

The only preparation for this simple proceeding is thorough evacuation of the bowels beforehand; and the only after-treatment requisite is an opiate, to lessen pain and prevent any action of the bowels, followed by a dose of castor-oil in two or three days. The relief afforded by section of the mucous membrane is almost instantaneous, and the patient feeding well, daily regains health and spirits. In the course of two or three weeks, the wound will probably have healed. A slow-healing wound may be advantageously touched with nitrate of silver, and the administration of the confection of black pepper has apparently a beneficial influence. The result of this superficial operation is usually a permanent cure, and with no evil consequences; whereas deep section or division of the sphincter ani muscle, is sometimes followed by loss of retentive power and involuntary defæcation. I have known a patient, in this condition after operation, pass a motion on coming into the consulting room; the contents of the bowel slipping away from him in the mere act of walking or standing.

**HÆMORRHOIDS—EXTERNAL—INTERNAL, WITH PROLAPSUS OF THE RECTUM.**—Hæmorrhoids, commonly called Piles, are essentially an enlargement of the hæmorrhoidal veins, around the anus, or within the sphincter at the termination of the rectum. The pathology of hæmorrhoids will be understood by reference to the anatomical distribution of these veins. Situated between the muscular coat of the rectum and the thin mucous membrane,—in the sub-cellular texture; the hæmorrhoidal veins are naturally large and tortuous, have no valves, and form a looped plexus around the terminal portion of the bowel, just above the sphincter, with branches to the verge of the anus. Hence, these veins are principally submucous, partly subcutaneous. The greater number of them issue in the superior hæmorrhoidal vein, and thence, through the inferior mesenteric vein, enter the portal system; some of the veins, however, issue in the middle hæmorrhoidal vein, and thence, through the internal iliac vein, enter the general venous system. Hence, the circulation in the hæmorrhoidal veins is principally portal, partly systemic.

Hæmorrhoidal affections are commonly named distinctively according to their situation. Thus are recognised surgically, Hæmorrhoids;—subcutaneous and *external* to the sphincter,—around the margin of the anus; or submucous, and *internal*, within the sphincter,—at the termination of the rectum. In the latter situation, enlargement of the veins, forming internal hæmorrhoids, is accompanied with a tendency to descent and protrusion of the overlying mucous membrane, through the sphincter or anal aperture; constituting a form of Prolapsus of the Rectum. Practically considered, it will, therefore, be convenient to describe Internal hæmorrhoids and

this Prolapsus as one disease. The anal cutaneous integument has an analogous tendency to relaxation. The distinctive terms, external and internal Hæmorrhoids, are not always obvious; the one condition merges into the other, owing to the continuity of the hæmorrhoidal veins. Hence, an intermediate variety has sometimes been recognised, named *interœsternal* hæmorrhoids, situated partly within and partly without the Anus.

Pathologically considered, Hæmorrhoids—whether external, internal, or intermediate, are a dilated and varicose condition of the hæmorrhoidal veins; accompanied with more or less relaxation of the overlying mucous or cutaneous integument, of the rectum or verge of the anus, respectively. This state of these veins would, so far, be analogous to that of varicose veins in other parts; as of the spermatic veins in varicocele, or of the saphena vein in varicose veins of the leg. But there is this important peculiarity in Hæmorrhoids; their relation, partly to the general venous system, principally to the portal venous system. And this twofold venous relationship nearly corresponds to the situation of Piles, as external and internal, to the sphincter ani; and hence the usual designation of these affections of the hæmorrhoidal veins, as thus distinguished.

*External* Hæmorrhoids, at first consisting of one or more dilatations of the external hæmorrhoidal veins at the verge of the anus, undergo certain structural changes. The vein becomes thickened and the blood coagulated; thus forming a thickened sacculus enclosing a dark-coloured clot. Or, the dilated vein, containing fluid blood, may burst, and the blood being extravasated into the adjoining cellular texture, it becomes really encysted, no communication existing between the cyst and the vein. Another form of external pile has been described, as consisting of a congeries of small veins of uniform size, without any appearance of cells, and connected by a dense cellular texture. Plastic infiltration of the cellular texture takes place around either form of pile, investing the sacculus or cyst; and hypertrophy of the skin ensues. Ultimately, an old external pile undergoes atrophy or wasting, in respect to its venous constituent, leaving only the integument in the form of a loose pendulous prolongation of skin.

The *symptoms* of external Piles relate to these various stages of progressive development and decline of this hæmorrhoidal affection. It appears, at or near the verge of the anus, in the form of one or more small, rounded, or oblong tumours, which are soft and compressible, and of a livid blue tinge. When largely formed around the anus, a bunch of these venous swellings somewhat resembles Hamburgh grapes, to which they have been compared in appearance. They are accompanied with a painfully depressing sense of bearing-down fulness at the fundament, especially in the standing posture and after any straining effort of defæcation or micturition; heat, itching or smarting, add to the patient's discomfort. A crack occurring, sometimes, at the base of an external pile, the irritation and pain thus occasioned, aggravate the hæmorrhoidal suffering. When coagulation takes place in the sacculated venous dilatation, or in a cyst resulting from rupture of the vein and extravasation of the blood into the surrounding cellular texture; the tumour becomes solid, harder and proportionately incompressible; its colour also is less clearly blue, as the vein, cellular texture and skin, become thickened. The fold of skin, which contained the dilated vein, remains, as the vein subsides; and the tumour then presented is a loose, pendulous bit of anal integu-

ment. This result is simulated from time to time during the active state of an external pile; the tumour being loose and flaccid when empty in the interval of an attack, and again tense whenever congestion supervenes. In this state,—that of congestion, external piles are occasionally liable to *inflammation*, accompanied with increased enlargement of the hæmorrhoid, forming an oval tumour, tense, red, and acutely tender. Suppuration may ensue, converting the pile into an abscess; this bursting, the clot of blood escapes with the pus, and when the abscess closes, the venous dilatation usually becomes obliterated; thus reducing the pile to a small flap of integument. A fistulous opening sometimes remains, which might be mistaken for the orifice of a blind external fistula. Examination with a probe, as to its depth, will at once show the difference.

*Internal* Hæmorrhoids undergo a parallel series of structural changes. The lower or smaller veins of the plexus, and ultimately the larger veins higher up, are dilated irregularly or into pouches, filled with dark coagula, often compact and hard. A bunch of varicose veins, crowded in the lower ends of the longitudinal folds of the rectal mucous membrane, presents prominent projections of this membrane; thus deepening the pouches there existing, between the folds. A number of smaller dilated veins also, sometimes form in the short columnar processes which are situated in the spaces between the folds. Two or three of the larger prominences of the longitudinal folds meeting below, coalesce; forming a transverse fold just within the sphincter. The arteries, which are abundantly supplied to the lower part of the rectum, and have a longitudinal course towards the orifice where they freely communicate, also enlarge considerably. In old-standing hæmorrhoids, the mucous membrane and sub-mucous cellular tissue become greatly hypertrophied, and extremely vascular. Elongated processes of a polypoid form are thus produced; extending to an inch in length; and projecting transverse folds, an inch or more in width.

The *symptoms* contrast in two important particulars with external piles. At first, internal piles present no external appearance at the anus, but they not unfrequently bleed. Hence, the distinction commonly made of Piles into *open* and *blind*, as they bleed or not. The first symptom of internal piles, is generally, an attack of hæmorrhage, venous or arterial, and more or less profuse; merely tinging a motion, or escaping as a few drops of blood afterwards, or to the amount of several ounces. Accumulating within the bowel sometimes, the actual loss of blood from the system may be greater than appears at first sight. This discharge of blood is attended with, or preceded by, a bearing-down weight in the fundament, and more or less frequent desire to micturate. Straining efforts are made to evacuate the contents of the bowel, the passage of fæces being both difficult and painful; at length, hæmorrhoidal tumours, with mucous membrane, are protruded, or prolapsed to some extent at the anus, in the act of defæcation, accompanied with mucous discharge. They then exhibit remarkable diversities of appearance; according to their number, size, and condition. Commonly, there are three distinct prominent growths differing in size; one at each side of the anus, and a third in front, this, the perineal, being usually the largest. In old-standing cases, there may be four or five such projections. Their boundaries are generally well marked; or the piles merge into each other, forming a nearly circular protrusion. A single pile of large size, is sometimes the only protrusion, situated towards the front of the anus adjoining the perineum.

Consisting of bright red mucous membrane connected with a loose fold of integument, it often forms in young persons, especially women.

*Extruded Piles* present a variable appearance also, depending on their condition, as being *congested*, or *constricted* by the sphincter. In an inactive state, and in a relaxed state of the sphincter,—they form softish tumours of a red granular appearance, protruding just at the orifice of the anus; when fully protruded, tightly constricted and congested,—they are large, tense swellings of a deep red colour, and smooth surface, which readily bleeds. *Ulceration* occurs, occasionally; attacking the tumour in many points at once, but advancing seldom to any great extent. Bushe saw an instance of phagedænic ulceration; and in two cases, hæmorrhage of a florid character, supervened. *Mortification* and *sloughing* of the hæmorrhoids may result from complete strangulation by the sphincter; a process of natural cure which sometimes occurs, and, although attended with much suffering, it is free from any danger of hæmorrhage. Dr. Bushe mentions having seen a fatal result in one case out of four which he had met with.

When the hæmorrhoids are of large size, and fully protruded, the integument at the margin of the anus becomes everted, and forms a broad band girding the base of the tumours externally. The skin, thus everted, swollen, irregular, and of a livid colour, is liable to be mistaken for external piles; but its excision in an operation would probably be followed by serious contraction of the anus. External and internal piles often do co-exist; but then the sphincter, covered by integument, usually forms a narrow band separating the two. When, as sometimes follows, the two forms merge into each other, their difference may be recognised by the character of the integument,—skin or mucous membrane, at the line of junction; though I have seen this difference disappear in oft-protruded piles, as the mucous membrane by frequent exposure acquired the character of skin.

*Inflammation* of internal piles is apt to occur, under the irritation of a costive motion, a brisk cathartic, a slight excess of wine, or irregularity of diet; producing what is called an "attack of piles." Their inflammatory swelling is attended with a sensation of heat, weight, and fulness, just within the rectum; difficulty and pain in passing a motion, and distressing irritability of the bladder. Pain of a dull aching character, may be felt in the loins and down the thighs, leading to the supposition in females that the womb is affected. Febrile constitutional disturbance is often severe. Then protrusion takes place at the anus, in the act of seeking relief by stool, or in straining to empty the bladder; the extruded hæmorrhoids become constricted by the sphincter, and the congestion resulting from strangulation of the acutely sensitive inflamed piles, entails yet further suffering.

*Hæmorrhage* is liable to occur, before or after protrusion, and may bring speedy but temporary relief, the piles subsiding; and this natural blood-letting has been regarded as a salutary vent or safeguard in persons having an apoplectic tendency, or disposed to other visceral congestions. But the quantity of blood lost through internal hæmorrhoids varies considerably, from two or three tablespoonfuls, to several ounces or pints; and thus the patient's general health may be seriously reduced by oft-recurring attacks, aided by the almost incessant muco-purulent discharge, and the suffering incident to this hæmorrhoidal affection.

The hæmorrhoidal flux, or discharge of blood from internal piles, depends on a determination of blood to the rectum; whereby also the piles

progressively increase in size or grow, as often as it recurs. This afflux of blood and discharge may be periodical, occurring monthly, or at intervals of two, three, or six months; and it may be remittent or intermittent. It continues usually from three to six days, increasing in quantity up to the third or fourth day, and then lessening. Women usually suffer more from piles at the catamenial period; and the flux occurs chiefly at the time of the menstrual flow, or it may be compensatory for a deficient discharge from the uterus.

*Complications.*—Piles are frequently associated with other diseases of, or affecting, the rectum; such as prolapsus, fistula, or fissure; they are also connected with diseases of the urinary organs, as enlargement of the prostate, stone in the bladder, and stricture of the urethra; and with diseases of the uterus. In relation to both the latter classes of diseases, as pertaining to the bladder and uterus; hæmorrhoids are the result of the vascular communication of these organs with the rectum, principally through the hæmorrhoidal veins. This connexion is most direct between the prostate and rectum; and the straining efforts to relieve the bladder in diseases of this gland, or with stone or stricture, will necessarily dilate and engorge the hæmorrhoidal veins. In thus enumerating the more important complications of hæmorrhoidal affections, I exclude causative conditions of disease, as of the liver or other organs, in their relation to portal congestion.

*Diagnosis.*—Internal Piles must be distinguished from prolapsus of the rectum, occurring alone, from polypi of the bowel, and from condylomata about the anus. *Prolapsus* in the form of a rugous flap of mucous membrane, on either side of the anus, is most liable to be mistaken for protruded piles. But the semilunar form of these flaps, the extent of their base, the gliding feeling of the folded membrane between the thumb and finger, and the absence of erection and hæmorrhage; are all diagnostic signs. In *polypus*, its pedunculated character, large size, incapability of erection or collapse, pale red colour, and slight disposition to bleed, are sufficiently distinctive of every species of this growth. Moreover, mucous polypus has a very soft spongy feel; and fibrous polypus, a solid and firm consistence. *Condylomata* are readily distinguished from piles, by their flat shaped, soft and mucous character, or their warty appearance; and their occurrence in other parts, as the scrotum or vulva.

*Causes.*—All the causes of hæmorrhoidal affections operate by producing congestion of the hæmorrhoidal veins, chiefly by obstructing or retarding the portal circulation, and thence the return of blood from the rectum; or by inducing a determination of blood to that part. The *structure* of the hæmorrhoidal veins, as being unprovided with valves to break the weight of the column of blood, the large size and tortuous course of these vessels, and the formation of a close plexus of intercommunicating veins; constitute an hydraulic arrangement which predisposes to a slow circulation of the blood around the lower part of the rectum. So also the thin and yielding character of the mucous membrane overlaying the veins, and of the anal cutaneous integument below, constitutes a structural condition favourable to the production of piles, internal and external. The ordinarily dependent position of the rectum has a co-operative tendency. *Predisposing* causes are; age,—adult life, or middle age; sex—males rather than females are liable in adult life; but conversely, after cessation of the catamenial discharge, in later life; sedentary habits; climate—warm and moist, or changeable; period of the year—spring and autumn; hereditary predisposition; plethora, and the sup-

pression of other hæmorrhages; passions, whether violent or depressing; tight lacing, or the application of bandages to the lower limbs; sitting on stuffed or on pierced seats; and, as specially affecting the portal circulation;—habitual constipation, disease of the liver or heart, pregnancy, or the development of other tumours in the abdomen or pelvis, and the straining efforts at micturition, with disease of the prostate, stone in the bladder, or stricture of the urethra; and the habitual excess of venery. *Exciting* causes are principally of an irritant character, as affecting the intestinal canal and inducing a determination of blood to the rectum; stimulating purgatives, or enemata, excess of wine, spiced or other stimulating food, a costive motion, ascariides, diarrhœa; or external irritation, as hard riding on horseback.

*Terminations.*—The various terminations of hæmorrhoidal affections have already been alluded to in describing the external and internal forms of piles. Their issues may be thus enumerated; subsidence; or obliteration,—by coagulation, suppuration, ulceration, sloughing.

*Treatment.*—Remedial, as well as preventive, measures must have reference to the various causes of hæmorrhoids; and the removal of such causes will be suggested in many cases by their nature, whether predisposing or exciting in their action.

*Constitutional* treatment is both medicinal and hygienic. To relieve portal congestion; the bowels must be carefully regulated by mild aperients which shall influence the whole intestinal canal and promote the secretion of bile, and by attention to diet, with daily walking exercise,—excepting during an attack of piles when the patient will be sure to seek the recumbent posture. The state of the general circulation should, at the same time, be regarded; in plethoric persons, a depletory course of aperients and reduced diet being indicated; in weak, anæmic persons, a tonic and unirritating dietetic plan of treatment. Thus may be advantageously combined aperients and tonics. A daily dinner pill is a convenient mode of administration; consisting of the watery extract of aloes, compound rhubarb pill, and blue pill, with nux vomica. The watery extract dissolves more readily, and acts before reaching the rectum. Other forms to be recommended are in particular, a lenitive electuary; consisting of bitartrate of potash and precipitated sulphur, in equal parts, with perhaps a little confection of senna, and sufficient honey or treacle to form an electuary. A teaspoonful may be taken every night at bed-time. This I have been in the habit of ordering, for many years since, in hæmorrhoidal affections, and have almost invariably found it of great service. Taraxacum in large doses,—ten or fifteen grains, and Plummer's pill, are both efficacious agents for relieving the portal circulation through the secretion of bile; and the mineral acids, especially the nitro-muriatic, seem to have some influence in that way; while, as tonics they support the general circulation. The confection of black pepper, Ward's paste, has long been in great repute as a remedy for piles; a drachm dose being taken three times a day. It is supposed to act directly on the piles as a stimulant application, and might therefore be more advantageously introduced at once into the rectum. This was done by a patient of Sir Edward Home, as related by Sir B. Brodie, and it had the effect of curing him. Cubebs is also taken internally with the same view. I concur with Mr. Curling in not much recommending these remedies; and my experience is that such stimulants are more beneficial in promoting the healing of a sluggish wound after the operation for fistula or fissure in ano.

*Local* applications are important adjuncts to the constitutional treatment, and as a means of allaying pain. *External* piles may be sponged with cold water, or with some sedative and astringent wash, as weak lead lotion, or a weak solution of alum, sulphate of zinc, sulphate of iron, or of the muriated tincture. The unguentum gallæ is also beneficial. *Internal* piles are amenable to similar applications used internally as injections or lavements. Cold water alone, thrown into the rectum every morning, often proves very efficacious in constringing the dilated vessels and softening the motion which follows its use. Medicated astringent injections, as of iron or alum with decoction of oak bark, should be thrown into the bowel at bed-time, that during the night any such application may have time to act on the piles. But they should be weak solutions, as a grain of sulphate of iron to an ounce of water; and used in small quantity, only two or three ounces at a time. Citrine ointment is said to be very beneficial, when the hæmorrhoids are in an unhealthy state accompanied with a slimy discharge; a little of the ointment being inserted within the sphincter every night, by means of the finger, which the patient can himself accomplish. An ointment of nitrate of silver is also very useful, although liable to stain the linen.

When piles become *inflamed*, the patient must keep the recumbent position, and cold or warm applications will be appropriate. Pounded ice is highly recommended by Mr. Curling, who finds that it generally gives complete relief in a few hours. Warm fomentations or poulticing may be preferable, and if several piles be affected, a few leeches should be applied around the tumours. An external pile may be opened with a lancet, and the coagulum squeezed out; an abscess should be punctured and poulticed. Internal piles having *protruded*, they must be returned by gentle uniform pressure, to empty the piles of blood, and then to push them back within the sphincter. If tightly strangulated, they may be punctured in several places with a needle, and cold or iced water applied; and then with a little manipulation they will probably slip up. Prolonged strangulation and a tendency to sloughing, forbid any attempt at reduction; warm fomentations should be used.

*Operative Procedures.*—When piles are beyond the control of medical treatment, general and topical, or hæmorrhage from them is detrimental to health, operative interference becomes necessary. No such interference should be resorted to if the piles be in a state of active inflammation, excepting perhaps when they are quite external. Piles may be removed by excision, ligature, or cauterization. The first method is applicable exclusively to external hæmorrhoids; the latter two are appropriate for the removal of internal hæmorrhoids.

*Excision* is a simple operation, easily performed, and very effectual. The patient lying on his side with the knees well drawn up, and the buttocks held apart; the tumours are seized with a vulsellum or hooked forceps, and successively snipped off with scissors curved on the flat, and applied flatwise at the base of the tumour. Any loose, redundant portion of skin may be included in the excision, but all such integument should not be removed, lest the contraction of cicatrization might leave the patient with a strictured anus. Hæmorrhage is easily controlled by cold and the pressure of a pad, secured by a T bandage. A small spouting arterial vessel may be twisted. After the removal of an *inflamed* external pile, the bleeding relieves the symptoms, and then the part heals rapidly. This would be a most painful operation in the case of inflammation, unless

performed under the influence of chloroform; or of local anæsthetic agents, which are equally effectual, as ice and salt, or the ether-spray.

*Ligature.*—Internal piles should be removed only by ligature. It is the safest procedure—owing to the liability of hæmorrhage, and the most permanently curative,—in preventing the recurrence of hæmorrhoids with the accompanying prolapsus of the rectal mucous membrane. The operation is, however, not so free from the slightest risk, as Mr. Syme has represented. Erysipelatous inflammation may creep up the bowel; pyæmia and tetanus are also occasional consequences. The conditions of internal hæmorrhoids most fitted for this method of removal, are; where the tumours consist chiefly of large, prominent, globular or pedunculated, venous dilatations, having a dark-blue appearance; or where the tumours having a bright red colour, readily bleed, but the prolapsed mucous membrane is thickened or abundant. A marked tendency to uncontrollable hæmorrhage, in any case, will always render the operation requisite.

The bowels having been relieved by castor-oil or other mild aperient, an enema of warm water should be given shortly before the operation, in order that with its evacuation the piles may descend well into view. This effect may be aided by desiring the patient to sit over a pan of warm water, and bear down. Then, lying on the side most convenient to the operator, with his knees drawn up and the buttocks separated by an assistant; one of the tripartite portions of the protrusion is seized with a vulsellum (Fig. 427), double four-pronged forceps, or with the loop-

FIG. 427.

eyed forceps, and drawn downwards, inclining inwards so as to fairly expose the junction of the anal integument and mucous membrane. At this point, a deep notch or incision is made with a long, straight pair of scissors; applied just on the mucous-membrane side of the junction, as being far less sensitive, and taking care to cut along the inner side of the rectum and not into the pile. The depth of incision must be such as to reach the base of the pile; and if it be pedunculated, long arterial vessels will probably be seen coursing down to the stalk of the pile. The requisite depth is ascertained by the Surgeon moving about the portion of protrusion with the vulsellum, as he clips deeply with the scissors. Handing the former instrument to an assistant, a ligature of fine whipcord is

passed well into the notch, and carried round the root of the pile, and knotted so as to securely strangle it. Sometimes, the base of the protruded portion is too broad to be thus strangulated; then it must be transfixed, by passing a deeply-curved *nævus* needle armed with the ligature, through the base, and each half tied separately. Other portions of protrusion are ligatured in the same way. It is, however, unnecessary to include every portion of the thickened and prolapsed mucous membrane. An open surface is left of sufficient extent to prevent any redescend, as contraction ensues; further removal might induce a strictured condition of the rectum. Any external pile or redundant portion of anal integument, may be excised, observing the same precaution as to the extent of such removal. The ends of the ligatures are cut off close to the piles, or left long if hæmorrhage be likely to occur. In either case, the protrusion had better be returned into the rectum, otherwise the pain occasioned subsequently by the constriction of the sphincter will be more than that of the operation. If hæmorrhage occur, the ligature-ends, hanging out of the anus, will enable the Surgeon to draw the parts out again and secure any bleeding vessel. Chloroform is scarcely requisite in the operation as thus performed,—by cutting through the mucous membrane. The *after*-treatment is very simple; a full dose of opium the first night to prevent pain and any action of the bowels, and the liability to irritation about the neck of the bladder with spasmodic retention of urine. Hyoseyamus and camphor mixture will then also prove efficacious. A dose of castor-oil may be given on the third or fourth day; and one or two of the ligatures sometimes come away with the evacuation. The whole are passed in about a week; but still the patient should keep his bed for some days longer to insure the closure and contraction of the mucous surface, before the upright posture is resumed.

*Cauterization*.—This method of treatment is intended as a substitute for the ligature of internal piles, in certain forms of these hæmorrhoids. When the tumour is flat and sessile, of a bright red colour, and easily bleeds, its substance consisting more of small arteries than of dilated veins; a ligature is less readily applied to the base of such a shaped tumour, and cauterization with strong nitric acid is equally effectual in destroying the pile. So also if its mucous covering be granular or ulcerated; or without any decided hæmorrhoidal tumour, if the rectal mucous membrane be congested and relaxed, with a tendency to bleed; nitric acid proves very beneficial, especially in the latter condition.

Cauterization—by means of strong nitric acid, was originally recommended by Dr. Houston of Dublin, followed by Sir W. Fergusson; but in England, this method of treatment has been particularly advocated by Mr. H. Smith, and Mr. H. Lee. The acid is very easily applied. Protrusion of the pile may be caused as for the operation of ligature; or the application made through an anal speculum,—a tube open on one side, by which the diseased surface can be reached. A glass rod or brush dipped in the acid is rubbed freely over the surface, and the part dabbed with a piece of lint saturated with prepared chalk and water; the protrusion is then returned into the rectum, or the tube withdrawn. The only precaution should be to avoid touching the surrounding anal integument, for which purpose it may be well smeared with oil or grease, before applying the acid. Relief soon follows a single application in some cases, and it is unnecessary to confine the patient to bed; so that this might be termed the ready method of treatment as compared with ligature. But

its permanently curative efficacy may be doubtful. Cure seems to take place by coagulation of the blood within the pile, obliterating it, then the formation of an ulcerated surface by sloughing, which being succeeded by cicatrization and contraction, may gradually *brace* up the relaxed mucous membrane. It may, however, result in over-contraction; there is also some risk of erysipelatous inflammation as a consequence of cauterization, although not more probably than after ligature.

The *clamp* procedure is a combination of the treatment by ligature, and by nitric acid. The advantages of this method are; the avoidance of any danger consequent on ligature, and the shorter duration of treatment,—about two or three days. But the disadvantages seem to preponderate; it will probably be a less effectual operation, and there is the risk of hæmorrhage. The tumour is seized and compressed, with the clamp for a period of a few minutes; its free surface is then excised by a pair

FIG. 428.

of scissors, and the surface, thus exposed, is touched with the strongest nitric acid or with the actual cautery. The clamp is removed, and the parts being well oiled, the operation is completed. This method, practised for some years by the Dublin Surgeons, has been chiefly advocated by Lee and H. Smith; the latter Surgeon having devised an "improved clamp," worked by a screw (Fig. 428), so that pressure may be gradually taken off, and any bleeding vessel can be readily seen and secured.

The *écraseur* has been used for the removal of internal piles; a practice in vogue with some French Surgeons, especially Chassaignac; but which has not yet found much favour with Surgeons in this country. Although a painful proceeding, the freedom from hæmorrhage might recommend it; but the probable occurrence of stricture of the rectum after cicatrization, is a very grave objection to this mode of operation.

**PROLAPSUS OF THE RECTUM.**—*Structural Conditions.*—In connexion with internal hæmorrhoids, prolapsus of the rectum is an almost necessary accompaniment. The latter may, however, occur alone, and this protrusion through the anal orifice is sometimes called *prolapsus ani*; an incorrect designation, seeing that the anus as merely the terminal aperture of the rectum, cannot itself be protruded.

Prolapsus recti may happen in two forms. Usually, the *mucous coat* alone descends, owing to its loose connexion with the muscular coat; and the prolapsus then consists of an everted duplicature of mucous membrane. Occasionally, the *muscular coat* also descends with this membrane, constituting an everted duplicature of the whole thickness of the bowel. The possibility of this complete prolapsus of the rectum was formerly doubted by Copeland and other authorities, but the question is now set at rest by the existence of such a specimen in the Museum of King's College.

*Signs.*—The signs or appearances of prolapsus recti are very obvious; the protruded part has the ordinary vascular-red colour of mucous membrane, and is wet with mucus; the surface may be thrown into transverse rings or folds around the protrusion. Its shape varies, and apparently according to the extent of the part. Commencing usually in the form of one or two lateral folds of mucous membrane on either side of the anus, the protrusion soon becomes an unbroken ring, encircling the anus; as it enlarges, it may acquire a cylindrical shape, tapering somewhat towards its free end, and there present an orifice at the reflection of the membrane upwards, which leads into the bowel. This is now the anal orifice of the rectum. The extent of protrusion varies considerably; in children, reaching perhaps to six or eight inches; in adults being more limited, and having more of a globular than a cylindrical form. In old persons, the prolapsus frequently attains a large size, owing to the laxity of the sphincter. At either extreme of life,—infancy or old age, complete prolapsus of the rectum—involving the whole thickness of the gut, is more liable to occur.

The two forms of prolapsus may be readily distinguished; in the descent of mucous membrane alone, the protruded portion is continuous with that investing the sphincter; whereas, with invagination of the whole thickness of the gut, there will be a distinct and deep sulcus between the protrusion and the margin of the sphincter.

In *old-standing* prolapsus, the mucous membrane becomes thickened and leathery, involving the sub-mucous cellular tissue; the sphincter is much relaxed and the anal orifice as much enlarged, while the surrounding integument is thickened, redundant, and pendulous; facilitating the occurrence of prolapsus.

Sympathetic affections of other organs often accompany the depressing sense of bearing-down occasioned by the prolapsus. Irritability of the urinary bladder, or spasmodic retention of urine are frequently experienced, and much flatulent, dyspeptic irritation. Pain extends across the loins and down the thighs. These symptoms are aggravated, when the protrusion is recent and nipped by the sphincter, but the bowel may then recede spontaneously; a more chronic state of loose prolapsus, oft recurring and oft returned, is productive of perpetual suffering.

Congestion, ulceration and purulent discharge, are apt to occur; strangulation and sloughing have also been known to take place, and a natural cure may thus be effected.

The *causes* of prolapsus are predisposing, or exciting, in their operation. *Predisposing* conditions may be fairly expressed by the terms general debility with an atonic state of the intestinal canal. Thus, prolapsus of the rectum is met with most frequently in weakly children or adults, and who are the subjects of atonic, flatulent, dyspeptic symptoms. The *exciting* causes of this affection vary with the period of life; in childhood, ascarides or some other source of intestinal irritation, giving rise to diarrhoea, frequently results in prolapsus; in adults, constipation, and especially accumulation of faeces in the rectum, is the more common cause, aided by the straining efforts in defecation. The bowel comes down with each evacuation, and progressively enlarges. Other causes operate in a similar manner; stone in the bladder, exciting frequent and difficult micturition, is a cause of prolapsus at either extreme period of life; stricture of the urethra, and enlargement of the prostate, as life advances; and the latter especially in old age. The habitual use of

copious lavements has undoubtedly a prolapsing tendency. Internal hæmorrhoids result in prolapsus, by dragging down the overlying mucous membrane with them in their descent.

*Treatment.*—Having regard to the causes of prolapsus, its remedial treatment should be both constitutional and local, the latter including operative measures.

The *bowel* must, of course, be first attended to, when in a state of protrusion. Reduction is accomplished, in the recumbent position; by gentle and uniform compression of the protruded portion with both hands, using a soft towel to protect the mucous surface, and to prevent its slipping from under the fingers. There may be some difficulty in returning the bowel, when the protrusion is large or the sphincter tight. Chloroform may prove effectual for overcoming the resistance; or by introducing the finger into the bowel, it may pass up with the finger and not re-descend when it is withdrawn; but, in extreme cases, it may be necessary to partially divide the sphincter by inserting a straight narrow bistoury or tenotomy-knife between the bowel and the anal orifice. When the bowel is fairly returned, a pad of lint or piece of sponge must be applied over the anus, and retained *in situ* by a T bandage. A well-fitting rectal supporter or truss should be worn in old-standing, established prolapsus.

The *constitutional* treatment will vary with the cause of prolapsus. A tonic plan of treatment is always appropriate, but the state of the bowels must always be specially regarded. In *children*, and especially the ill-fed children of the poor; it will generally be requisite to correct an irregular action of the bowels or diarrhœa, as depending on improper diet, often an excess of vegetable food. The removal of this cause of intestinal irritation must be coupled with the administration of tonic purgatives, and the rectification of the intestinal secretions. Perhaps, the most generally useful form of combination, is rhubarb, hydrargyrum cum cretâ, and carbonate of soda or magnesia; taken as a powder every night at bed-time. Ascarides may be the source of irritation in some cases, or the diarrhœa may be sympathetic as depending on dentition. In *adults*, the habitual constipation usually present must be overcome by castor-oil, lenitive electuary, or bitartrate of potash; or by mild enemata, if the constipation be rectal. Stone in the bladder, enlarged prostate, or stricture of the urethra, will obviously require attention, when prolapsus depends on these causes.

*Local* treatment, of a medicinal character, consists chiefly in the use of astringent injections, to correct the relaxed state of the mucous membrane. For this purpose, the decoction of oak bark, with alum, in the proportion of a scruple of the latter to eight ounces of the decoction, will be sufficiently astringent; and a third of the quantity enough for an injection. The muriated tincture of iron, a drachm to a pint of water, is also an excellent astringent; two or three ounces being thrown up, or more according to the age of the patient. Mr. Curling usually prescribes the one formula, Sir B. Brodie preferred the other. Infusion of rhatany or a solution of tannic acid, may also be employed with advantage. Any injection should be used cold, and allowed to remain in the rectum for some time, which is more conveniently done at bed-time. A *diseased* state of the prolapsed mucous membrane must be managed on ordinary principles. Thus, an ulcerated surface may be brushed with a solution of nitrate of silver.

*Operative* procedures are resorted to for the cure of inveterate prolapsus.

They are excision, ligature, and cauterization. The object is to produce such an amount of contraction, by the healing of a wounded surface, or after slight sloughing of the mucous membrane, as shall effectually and permanently brace up the previously prolapsed part.

*Excision*, as first proposed by the late Mr. Hey of Leeds, consisted in removing only the loose and pendulous flaps of skin around the anus; but Dupuytren's modification consists in removing also portions of the mucous membrane. This procedure is certainly requisite, when the prolapsus is large, and the membrane thickened. The patient lying on his back and the legs trussed up as for lithotomy; a fold of skin and mucous membrane, at the side of the anus, and more or less broad according to the laxity of the part, is seized with a vulsellum, drawn a little forward, and excised with a curved pair of scissors. This is repeated on the other side, thus forming two oval wounds, longitudinally; and sometimes further portions may require removal. Any bleeding arterial vessel should be twisted or tied; lest hæmorrhage occurring after the operation, bleeding may take place into the bowel and escape observation.

*Ligature* was originally proposed by Mr. Copeland. It is especially adapted for a condition of voluminous and lax mucous membrane—associated perhaps with internal hæmorrhoids—but unaccompanied with any or much participation of the anal integument. The operation is easily performed, by seizing with a vulsellum selected portions of the mucous membrane, and casting a whipcord ligature around each; cutting off the ends of thread, and returning the whole within the sphincter.

*Cauterization* is usually effected by means of strong nitric acid, and this method of treatment was much advocated by Sir B. Brodie. It has since been employed in many cases; Mr. Ashton has applied the concentrated acid with the "happiest result," and Mr. H. Smith has found it act like "a charm." There can be no doubt about the truth of these representations, qualified as they are by specification of the appropriate conditions of prolapsus. Nitric acid is suitable in the same condition as that fitted for ligature; but it is specially applicable when the mucous membrane is extremely vascular,—of an arterial character rather than venous, presenting a velvety appearance; or again when the surface has an unhealthy, ulcerated appearance. The acid is applied by means of a glass brush; care being taken to protect the surrounding parts with thick oil or grease, and to dab away any excess of acid from the diseased surface.

Chloroform may be administered in any of these operations, not so much for its anæsthetic influence, as to relax the incessant action of the sphincter.

**POLYPUS OF THE RECTUM.**—Any growth springing from the mucous membrane of the rectum, and attached by a narrow and elongated pedicle, is named a *polypus* of the rectum. The tumour, thus characterized by its stalked shape, differs in structure from simple hypertrophy of the mucous membrane, which is also occasionally pedunculated.

Polypus-growth varies in *structure* and *appearance*, forming different species, which have been variously named by authors on this subject. They may be described as;—(1) the *vascular* polypus; (2) the *villous*, an extremely vascular growth; (3) the *lobulated*, also vascular, and semi-malignant; (4) the *fibro-cellular* or *mucous* polypus; and (5) the *fibrous* polypus. The first four species are soft in consistence, and the vascular forms are prone to bleed; the fifth is hard, and comparatively bloodless.

In point of situation, any form of polypus springs from the mucous membrane within the sphincter ; but generally at the lower part of the rectum, ranging from about an inch to three inches from the anus. The size varies in different species; the ordinary vascular polypus being about the size of a pea or a cherry, the villous species attaining to that of an orange. This form of polypus has been specially described by Mr. Quain. Polypus-growth is usually single, but more than one or several may form. The period of life varies, and principally in relation to the species of growth. Vascular polypus is the form commonly met with in children; other species occur chiefly in adults,—a villous polypus in the rectum of a man, aged seventy, was not detected until about five years previously. The specimen is preserved in the Museum of St. George's Hospital. Generally speaking, polypus of the rectum occurs most frequently in children, according to Sir A. Cooper's experience; in adults, according to the observations of Bushe and Syme.

*Symptoms.*—The general symptoms of rectal polypus are those referable to the presence of a foreign body in the rectum. A sense of weight and fulness, with tenesmus and mucous discharge; is followed by protrusion of the growth when an evacuation occurs, and spasmodic contraction of the sphincter, if the tumour be situated in the anus or is attached by a long stalk higher up. As a growing polypus enlarges, diarrhœa, flatulent distension of the bowels, irritability of the bladder, and other sympathetic affections supervene. Obstruction of the bowel produces variously contorted or figured fœces, and sometimes leads to almost complete retention of the fœces, with intestinal distension. This result happened in the case of the villous growth just alluded to.

In addition to these symptoms of mechanical origin; hæmorrhage recurring from time to time, is characteristic of the vascular forms of polypus, as distinguished from those which bleed less readily. Malignant vascular polypus is attended, moreover, with certain peculiar symptoms; pain, lancinating and extending up the sacrum and down the thighs, amounting to scalding agony when a motion passes; copious bloody, fetid purulent discharge, as ulceration supervenes; and the sallow cachectic emaciation of advanced cancerous disease.

Examination of the polypus-growth will determine the particular species; and this can be accomplished, either by injection of warm water, causing the tumour to protrude with the evacuation, or by examination *in situ* with the anal speculum.

*Treatment.*—Removal of the growth offers the only prospect of cure. Ligature is preferable to excision, particularly as regards the vascular forms of polypus. Sir A. Cooper and Mr. Syme concur in the advisability of this method of removal. The bowels having been acted on as far as possible, to prevent the necessity of any relief for some days after operation; the tumour is made to protrude as for examination, when it must be seized with a vulsellum and drawn down, until its peduncle is fairly seen; a ligature is then applied around its origin, and the stalk cut off beyond by a pair of scissors, observing not to cut too closely lest the ligature should afterwards slip off. A broad-stalked polypus had better be transfixed at its base, by a needle carrying a double ligature; each portion is then tied. When situated high up the bowel, and out of reach with the fingers; the ligature must be passed by means of a double canula, or through a gum-elastic catheter, as in ligaturing polypus of the uterus.

STRICTURE OF THE RECTUM.—*Structural Conditions.*—The rectum, like

other mucous canals, is subject to contraction or narrowing of its calibre. This state may result from either of two conditions,—simple *fibrous* thickening, or *cancerous* thickening, of the coats of the bowel. These two conditions of stricture differ widely in their nature, symptoms and treatment.

(1) *Fibrous Stricture*.—This condition of stricture presents a prominent ring within the cavity of the rectum, entirely or partially surrounding the cavity of the bowel. It consists apparently of a fold of thickened mucous membrane, but principally of fibrous condensation of the sub-mucous cellular tissue; occasionally, there is co-existing hypertrophy of the muscular coat, rarely any change in the peritoneal investment which generally retains its healthy structure. The structural alteration is sometimes limited in extent, presenting an *annular* stricture; more frequently, the induration extends from half an inch to two or more in length, reaching to three or four inches, or even nearly the entire length of the rectum. If the thickening is greater on one side of the bowel than the other, the passage assumes an irregular winding shape. In rare cases, the contraction of the canal seems due to muscular action, no structural change having been discovered in the coats of the rectum; and also rarely, it is owing to the formation of fibrous bands across the cavity of the bowel, the wall of the gut remaining unaffected. Specimens of both these conditions of stricture exist, the one in the Museum of St. Bartholomew's Hospital, the other in King's College Museum. The *situation* of fibrous stricture is commonly at the lower part of the rectum, from an inch and a half to two inches from the anus, and easily within reach of the finger; next in order of frequency, at two to three inches distant from the anus; occasionally at four or five inches; and sometimes at the junction of the bowel with the sigmoid flexure of the colon. Very rarely, two distinct strictures have been met with; two such cases were seen by Mr. Curling, one of which originated in dysentery. *Above* the seat of stricture, the rectum is usually dilated, and thickened just above the part diseased. This thickening is owing to hypertrophy of the muscular coat, in consequence of the increased functional action of the bowel at this point to overcome the obstruction. The mucous membrane, above the stricture, is rarely healthy; being either unduly vascular, or ulcerated and pus-discharging. Ulcerated apertures may at length lead downwards along fistulous passages which open externally near the anus, or in the front of the perineum, or posteriorly as far off as the buttock. Sometimes, a fistulous communication forms between the rectum and the vagina or the urethra; and occasionally between the bowel and the cavity of the peritoneum. *Below* the stricture, the coats of the bowel are less changed; but there is frequently diffuse ulceration of the mucous membrane, perhaps hæmorrhoids, or a complete fistula in ano.

*Symptoms*.—Stricture of the rectum commences insidiously. The earliest symptom is that of some mechanical obstruction to the passage of the feces in the act of defæcation. Hence, frequent constipation ensues, with straining efforts at stool. This difficulty may be readily overcome by a solvent purgative, and the nature of the case remain unsuspected. But the feces become more scanty, narrowed or figured, and often voided in small lumps. Fæcal and flatulent accumulations above the stricture give rise to abdominal distension; while an irregular, feculent and mucous diarrhœa occasionally relieves the otherwise habitual tendency to constipation. In the *ulcerative* condition; scalding pain, and bloody, slimy

mucous or purulent discharge, are superadded to the symptoms of obstruction. Examination per rectum will affirm or negative the presence of stricture. On introducing the fore-finger into the rectum, the stricture can generally be felt; when its nature,—whether fibrous or malignant, perhaps the degree of contraction, and its extent, may also be determined. If situated beyond reach of the finger, the introduction of an oiled wax or gum-elastic bougie may possibly enable the Surgeon to ascertain the presence of a stricture, but not its nature; also its height from the anus, the degree and extent of contraction,—by observing the relative length, the size and obstructed portion of the bougie. In using the instrument, all these particulars must be gained very cautiously;—the curve of the rectum from before backwards and its inclination to the left high up, being duly remembered; also the promontory of the sacrum against which the point of the bougie is apt to impinge, and the presence of the natural folds of mucous membrane which may intercept its progress. Unless these circumstances be observed,—as to the course and character of the canal, some degree of obstruction might convey the impression of stricture. Indiscriminate pressure might then rupture the mucous membrane and open the peritoneal cavity; the point of the instrument seeming to pass, really turns downwards into the rectum.

The *causes* of fibrous stricture relate to its pathological origin. It proceeds from chronic inflammation of the mucous membrane and sub-mucous cellular tissue; resulting in fibrous deposit, especially affecting the latter texture. Ulceration or abrasion of the mucous membrane, resulting in contraction, may also produce stricture. The *exciting* causes are necessarily various; any source of irritation, as the impaction or passage of hardened fæces, foreign bodies as fish-bones, &c.; or the straining efforts in forcible defæcation. Syphilis has undoubtedly been known to produce stricture of the rectum, either as a primary or secondary affection. In women, difficult parturition or the unskilful use of instruments for delivery, may induce inflammation. Of 28 cases of stricture of the rectum which came under Mr. Curling's observation, 20 were women; and in 9 of them, the stricture commenced after labour, some of which were distinctly attributed to an injury at the time. The greater liability of females to this disease, accords also with the experience of Mr. Copeland and of Dr. Bushe. An external injury to the part has occasionally been the cause, as a severe kick in the fundament.

*Treatment.*—The principle of treatment is mechanical *dilatation* of the stricture. Considerable judgment is requisite in carrying out this treatment. Besides attention to the natural course and character of the canal and the nature of the stricture; two additional rules should always be observed in using dilatation,—namely, never to make any forcible effort, and never to cause pain. The instrument used should always pass with ease. The bowels should be kept free by mild aperients, especially castor-oil.

When situated *low down*, dilatation may be effected with tolerable facility, by the introduction of a proper-sized gum-elastic bougie, or compressed sponge-tent. Either form of dilator must be allowed to remain in the stricture; the bougie for ten or fifteen minutes, the tent may remain for twelve or twenty-four hours. Dilatation must be renewed every two or three days, and with progressively increasing sized instruments. Tent-dilatation is, however, the most effectual, owing to the swelling character of the compressed sponge. A very tight annular or

almost membranous stricture may be advantageously notched with a protected bistoury,—my “concealed fistula-knife” being serviceable for this purpose. The posterior aspect of the canal is the safest for a slight incision, not to endanger the peritoneum. Dilatation can then be pursued by a bougie or tent. Various other dilating instruments have been devised, by Weiss, Bushe, Arnott, Sir C. Bell, Charrière of Paris, Nélaton, Bermond, Todd, Costallat, and Coxeter; all of them are ingenious, yet not so efficient as the bougie.

If the stricture be situated *high up*, the same treatment may be adopted, but with very great caution. A wax or a very flexible gum-elastic bougie should be used. Pain or spasm ensuing from the use of instruments, admit of relief by the occasional introduction of opiate suppositories. But however temporarily successful dilatation may prove, a permanent cure is seldom if ever effected. Dupuytren, Bushe, and Dr. Colles of Dublin, emphatically concur in the same opinion; Mr. Curling takes a more favourable view of this plan of treatment. Undoubtedly much will depend on having to deal with fibrous stricture in an early stage of its formation, and in prolonging the course of dilatation for some weeks or months after apparent cure.

*Palliative* treatment affords relief to the pain and discharge. Nitrate of silver, in the proportion of five grains to the ounce of distilled water, or the mild citrine ointment, may be applied with advantage to the diseased mucous membrane within the stricture, by means of a camel-hair brush passed through an anal speculum. Hæmorrhage may be restrained by cold alum or other styptic injections, administered through a long tube.

In extreme cases, of almost complete obstruction, Amussat's operation of colotomy must be resorted to.

(2) *Cancerous Stricture*.—The coats of the rectum are liable to the formation of every species of cancer—scirrhus, encephaloid, colloid, and epithelial; resulting severally in stricture of the bowel. Any such growth forming external to the rectum may so press upon and implicate the bowel, as to have the same effect. The disease is usually situated at the lower part of the rectum, within three inches from the anus; less frequently, at the junction of the sigmoid flexure of the colon; but any portion of the bowel may be affected.

*Symptoms*.—Commencing insidiously, the early or mechanical symptoms of obstruction are similar to those arising from fibrous stricture. But, the excruciating pain, its lancinating character, darting up the sacrum and extending down the limbs, the aggravated intensity of the pain, as of molten lead, when the fæces pass, and especially when ulceration has supervened; with the increased tendency to hæmorrhage, and copious, fetid purulent discharge;—these symptoms, are somewhat diagnostic of cancerous stricture. Subsequently, the peculiar cachectic appearance and emaciation are distinctive constitutional symptoms. Examination per rectum will probably determine the diagnosis. If the disease be situated as usual,—low down; on introducing the finger into the bowel, considerable thickening of the bowel and narrowing of the passage are felt; but the consistence of this diseased portion of the bowel differs widely;—the resistance being that of cartilaginous induration,—in scirrhus stricture, and resembling a soft cushion,—in encephaloid or other soft cancerous stricture. If the finger can be insinuated into the stricture, an irregular nodulated surface is felt, and which is more exten-

sive than usually in fibrous stricture. Sometimes, nodules,—hard or soft are found, round about the seat of stricture. On withdrawing the finger, it is covered with blood and pus. Fistulous communications form between the bowel and adjoining parts,—the vagina, bladder, or urethra, which also become implicated. The lymphatic glands in the neighbourhood of the rectum become enlarged, and secondary cancer may be developed in other internal parts,—the lumbar glands, peritoneum, or liver. Death results from fecal obstruction, or from these complications.

The liability to cancer of the rectum varies with the *period of life*, and *sex*. It occurs generally, in middle life, and women are said to be more subject than men. This latter predisposition seems doubtful. Of 21 cases, noted by Mr. Curling; 17 were males, and only 4 females. Again, of 11 cases, noted by Mr. Baker in the *Med.-Chir. Trans.*, vol. xlv., 8 were males, and only 3 females. Of 35 cases at St. Mark's Hospital, as recorded by Mr. Carter; 19 were men, and 16 women.

*Treatment.*—*Palliative* measures are alone practicable. They consist chiefly in a light nourishing diet and a tonic course of treatment; with regulation of the bowels and solution of the feces by castor-oil and other mild aperients, and opiates administered internally, and per anum by injection or suppository, to assuage pain. Chloroform applied locally to the anus by means of a piece of lint covered with oil silk, or inhaled as usual, has given marked ease, although not pushed to the extent of insensibility; and its anæsthetic influence may be resorted to daily, if necessary.

The introduction of any instruments is always hazardous. Bougies and tents must not be thought of; feculent accumulations above the strictures may sometimes be reduced by passing a long tube through the stricture, and then giving an injection of warm water. But this proceeding must be conducted with the utmost caution.

Excision of the cancerous mass was proposed and practised by Lisfranc; and afterwards by Dieffenbach with success in no less, it is said, than thirty patients, not one of whom died in consequence of the operation. Nevertheless that such a procedure is justifiable, may well be doubted. Colotomy, in the left loin, seems a far more Surgical resource, both as a means of relieving misery connected with the rectum and of prolonging life.

**RECTAL FISTULA.**—Fistulous communications are liable to form between the rectum and adjoining organs; the bladder, as Recto-vesical Fistula, in the male; and the vagina, as Recto-vaginal Fistula, in the female.

(1) *Recto-vesical Fistula* is not often met with. It may result from disease, forming an ulcerative communication between the rectum and bladder, as in cancer of the gut; or be of traumatic origin, as from a wound of the bowel in the operation of lithotomy.

*Signs.*—The escape and discharge of the contents of either organ,—of urine *per anum*, and of feculent matter and flatus *per urethram*, at once proclaims the nature of the lesion; while digital or ocular examination through a double-bladed anal speculum, will plainly detect the situation and size of the fistulous opening. When resulting from disease, the cancerous or simple nature of the fistula, can thus also be readily discovered. Constant irritation, excoriation, and offensive odour, accompany the discharge of urine and feculent matter; the patient leading a life of seclusion and misery.

*Treatment.*—The object is to close the fistulous opening; but the

Surgical procedure appropriate for this purpose, must depend on the cause and extent of the opening. *Cancerous* fistula is incurable; and all that can be done is to palliate the patient's suffering, by opiate and detergent injections, with constitutional support. *Traumatic* fistula, if recent, and of small size, may perhaps be induced to contract and close; by introducing a pencil of nitrate of silver occasionally, or by means of the actual cautery,—a red-hot wire, or platinum wire heated by the galvanic current, as devised by Mr. Marshall; an anal speculum being used to protect the bowel, and effect the cauterization exactly within the fistulous opening. An old, callous fistula, and of larger size, cannot be closed in this manner; it will be necessary to lay it open, and convert the rectal or anal into a perineal fistula, so that it may granulate and heal from the bottom. This is accomplished by passing a grooved staff through the urethra, and cutting down upon it; dividing the sphincter and intervening portion of bowel. A strip of lint is then placed in the wound.

(2) *Recto-vaginal Fistula* is usually of traumatic origin; the result of sloughing of the posterior wall of the vagina, from long-continued impaction of the head or the use of instruments during parturition. The size of the opening varies considerably, from that of a small perforation to a large portion of the posterior vaginal wall. It may be complicated by laceration of the perineum.

*Signs.*—The discharge of feculent matter and flatus from the vagina at once shows the existence of a recto-vaginal communication; and examination with the finger, or inspection by introducing the duck-billed speculum, will reveal the situation and extent of the aperture.

*Treatment.*—The procedure for closing a recto-vaginal fistula must be determined primarily, according to whether the opening be simple, or complicated with laceration of the perineum.

*Simple Recto-vaginal Fistula*, if recent, and of small size, may perhaps be closed by cauterization gently with nitrate of silver, a red-hot wire, or the platinum loop, applied within the opening; the anterior wall of the vagina being well raised by the duck-billed speculum. An old fistula, and of larger extent, must be closed by a plastic operation. The bowels having been thoroughly emptied by aperients, and an enema on the morning of operation; the duck-billed speculum is introduced and the fistula, in the posterior vaginal wall, entirely exposed; the patient lying recumbent, with the legs raised and held apart, and the buttocks at the edge of the table, as for lithotomy. The Surgeon sitting opposite the perineum, he freely pares the margin of the opening; then, the edges are brought into even and easy apposition, transversely to the axis of the vagina; to effect which it will be necessary to divide the sphincter ani on either side, in order to overcome tension, and spasmodic muscular contraction after the operation. The sides of the opening are evenly secured in apposition by means of silver or platinum wire sutures; taking care to transfix the whole thickness of the gut, excluding its mucous membrane, and observing to bring the sutures through the vaginal mucous membrane half an inch beyond the pared edges, above and below. The sutures are fixed by a close twist of the wire across the line of aperture; or they may be passed through a perforated leaden shield, overlaying the aperture, then through split shot, and clamped with forceps close upon the shield, so as to fix it upon the vaginal wall. The ends of wire are snipped, and the operation completed. *After-treatment* is most important. It consists in preventing any action of the bowels for a week

or ten days, by keeping the patient under the influence of opium, until firm union is established. A laxative aperient, or an enema of castor oil and gruel, may then be administered. Cleanliness is also essential to success; the vagina being syringed with cold water, two or three times a day, and the urine drawn off by a catheter as occasion requires. About the end of a week, the sutures may be snipped through, and gently withdrawn. A small aperture, even a pin-hole opening, not unfrequently remains, and obstinately resists closure. This must be treated, as already described, by touching with nitrate of silver or the wire-cautery.

The *complication* of a *Lacerated Perineum* must be treated by the appropriate operation, described in connexion with that condition; the fistulous aperture being closed by paring, and sutures. I have thus succeeded in closing a recto-vaginal fistula, and subsequently a laceration of the perineum, which occurred in the same woman; and in whom also a tight annular membranous stricture of the rectum was cured, by dividing its free margin with scissors, at two or three points of its circumference, and which I then dilated as usual, by the occasional passage of a bougie.

(3) *Entero-vaginal Fistula* is a rare occurrence; a communication having formed between the small intestine and the vagina. This condition would simulate a recto-vaginal fistula; but it may perhaps be distinguished by the feculent discharge having a more yellow colour, and less stercoraceous character.

Such fistula is *incurable*. An operation has been performed by Roux and Casamayor, with the view of establishing a communication between the small and large intestine; but the deep and difficult dissection necessary for this purpose, has proved fatal.

**ANAL TUMOURS.**—Various forms of tumour and excrescence are liable to beset the Anus. They are principally; epithelial cancer, fibrous tumour, warts and condylomata. The nature of these growths is the same as when occurring in other parts of the body, and they are recognised and diagnosed by similar symptoms as in other regions.

The *treatment* is excision, which may generally be effected most conveniently by a stout pair of scissors curved on the flat. Chloroform, ice and salt, or the ether-spray, will be requisite; the operation being acutely painful, and spasmodic action of the sphincter interfering with its performance. Wet lint dressing is often sufficient; but a persistent oozing hæmorrhage must be arrested by application of the perchloride of iron or other styptic, and sometimes by the actual cautery, with a compress and T bandage. Subsequently, great cleanliness should be observed, to prevent any irritation which might induce reproduction of the morbid growth.

**ANAL CONTRACTION**, or stricture of the anal orifice, results from tight cicatrization, in consequence of the healing of ulcers or wounds of the anal integument. This may occur after operations of excision; as the removal of external piles, or of anal tumours.

The only *treatment* is dilatation, gradually effected by bougies or compressed sponge-tents. It is remarkable how small an opening will suffice for the purpose of adequate defæcation.

#### INJURIES OF THE RECTUM.

**Wounds.**—The Rectum is liable to *wounds* or *laceration* by external injury, as a severe kick in the fundament, or the introduction of a foreign

body; but more commonly from internal causes, as during straining efforts of defæcation, and the passage of large and hardened fæces, or in parturition. Wounds of the rectum may occur also accidentally, as in lithotomy, or unskilful catheterism; or surgically, in the operation of puncturing the bladder through the trigone vesicæ for the relief of retention of urine. Injury by wound or laceration may involve the whole thickness of the wall of the rectum, or the mucous membrane only; and it is evident that the lesion may vary in direction, as being vertical or transverse.

The *symptoms* will be sudden pain and hæmorrhage, occurring in connexion with some occasion of injury; and examination per rectum, may discover the seat and nature of the lesion. Defæcation is painful and the fæces are streaked with blood; and subsequently with pus, when suppuration ensues. Granulation and cicatrization follow, or the wound becomes an ulcer of the rectum.

*Treatment* consists, in keeping the bowels easy and free by mild aperients or emollient enemata, and the avoidance of stimulating food; with rest in the recumbent position. Cleanliness, after each evacuation, will do much locally to promote healing; but an intractable sore or ulcer should be brushed over with a solution of nitrate of silver occasionally. It may become necessary to make an incision through the mucous membrane, along the ulcer, as directed in the treatment of fissured anus.

*Foreign Bodies.*—All sorts of foreign bodies may be found in the rectum; having been swallowed, or introduced directly into the bowel through the anus, and sometimes maliciously. By either mode of entrance, the list of such substances on record is most numerous and diverse in their nature; and their variety is increased by those formed in the body and impacted in the rectum. Hence, may be found; concretions,—biliary, intestinal and fæcal; of substances swallowed,—the bones of fish and small bones, stones of fruit, coins, pins, needles, knives, nails, sealing-wax, cedar pencils, brown paper, &c.; and as introduced through the anus,—pieces of stick, ivory, cork, horn, metal, rings, ferrules, bottles, pots, cups, a shuttle with its roll of yarn, a knitting-sheath, a pig's tail, a broom-handle, the leg of a chair, &c.

The *symptoms* of any such foreign body impacted, will be pain, hæmorrhage, and obstruction; on examination, it will be found within the rectum, and sometimes sticking out of the anus. Any sharp spiculated body occasions the acutest agony, especially on the slightest motion, so that the sufferer becomes afraid to move. In one such case, the patient crawled into my consulting room, looking the picture of misery, and could only point backwards to the fundament. On examination, I immediately introduced my finger into the rectum, when about two inches from the anus, I touched a bar lying across the bowel and stretching it out at a point on either side. I dislodged this bar with a twist and withdrew it through the anus. It proved to be the rib-bone of a rabbit. The patient remembered having eaten rabbit a few days previously, and the night before I removed this faithful rib, he was suddenly seized with excruciating pain in the lower part of the bowel, aggravated as he rolled about with suffering during the night. The relief was instantaneous, leaving only a dull aching sensation which wore off in a day or two.

*Treatment* in any case must, of course, be extraction of the foreign body, as soon as possible. But this may be difficult to accomplish, according to the situation of the body, its size and nature.

Concretions offer some advantage over other substances. Emollient enemata of soap and water or olive oil, may do something towards softening feculent masses; thus facilitating their extraction or discharge, piecemeal. They can then be scooped out with a lithotomy-scoop or a table-spoon. Other foreign bodies present special difficulties, and each almost its own peculiar difficulty. Removal is effected by the finger or the hand, coupled with dilatation of the anus which admits of gradual enlargement so as to pass the whole hand; or instruments may be necessary. The *modus operandi* must then be left to the ingenuity of the Surgeon. Sir W. Fergusson extracted a bougie from the rectum of an old gentleman, by means of lithotomy forceps. In another case, which Mr. Liston relates, a pig's tail had been mischievously thrust by some students into the rectum of an old woman; the bristles were in the wrong direction for extraction of the tail, and by sticking into the mucous membrane, it resisted any attempt. At length, a tube was slid up between the bowel and the tail, when the latter was easily withdrawn. In other cases, it has been found necessary to divide or break the substance in order to remove it. And in yet other cases, removal has not been accomplished by any manipulation or instrument. Whether the foreign body be extracted or not; in not a few cases death has ensued from violent intestinal inflammation.

#### CONGENITAL MALFORMATIONS OF THE ANUS, AND RECTUM.

*Imperforate Rectum*, as a congenital malformation or deficiency, may exist in two primary conditions; imperforate anus; or, the anus leading into a cul-de-sac, imperforate rectum. The former condition—imperforate anus, presents five varieties; (1) simply membranous obstruction of the anus; (2) with partial or complete deficiency of the rectum; (3) communication with the neck of the bladder or the urethra, in the male; (4) communication with the vagina in the female; (5) external communication, or fistula. The latter condition—imperforate rectum, presents two varieties; (1) membranous obstruction; (2) partial or complete deficiency of the rectum.

*Signs.*—When, after birth, there is no *evacuation* during the first thirty-six or forty-eight hours, of the usual dark-coloured meconium fluid, and perhaps sickness co-existing, the medical attendant or the nurse, is led to discover that the *anus* is *imperforate*; if indeed this deficiency had been overlooked at the time of birth. The condition of the rectum, when obstructed, is almost sure to be undiscovered at birth; but if *no bulging* in the fundament be perceived after some hours have elapsed,—the anus being imperforate—the lower end of the *rectum* will probably be deficient. *Imperforate rectum* is distinguished by the presence of an anal cul-de-sac. The finger can sometimes be introduced into this sac to the extent of its depth,—half an inch to an inch and a half. Those varieties of imperforate anus in which a *communication* exists, with the bladder, the vagina, or externally, admit of less direct recognition during life. But the discharge of feculent fluid through the urethra, the vagina, or an external fistulous opening, will be severally diagnostic of these malformations. In the latter state, the situation of the opening varies in the two sexes. In the male, the fistulous opening may be in the perineum just behind the scrotum, in the scrotal raphé, or anterior to the scrotum. In the female, it occurs in the perineum close to the vagina, or at the posterior commissure of the vulva. In both sexes, and in all these situations,—vesical, vaginal, and perineal, the vent is insufficient and defæcation

more or less difficult. Hence, constipation and intestinal dilatation ensues, especially as the faeces acquire consistency, and sooner or later, life becomes endangered.

All the foregoing malformations seem to occur more commonly in male children than in female. Thus of 100 cases collected by Mr. Curling, 68 were males and 32 females. But of 100 cases recorded by M. Bouisson, 53 were females, and 47 males. So, therefore, the liability of sex is doubtful.

*Treatment.*—Operative interference is necessary or becomes necessary, to preserve life, in consequence of the anal or rectal obstruction; or to remove a wretched and disgusting infirmity, in the cases of fistulous communication, or of an external perineal opening. The principle of operation, is to remove the obstruction by the formation of an anal opening in the situation of the natural anus,—the establishment of an artificial anus in the natural situation; or by the enlargement of a fistulous communication at a distance off,—in the left iliac region, or the left lumbar region, respectively, by Littré's or Amussat's operations.

*Imperforate Anus*, as a simply *membranous* obstruction, may be easily remedied. The integument over the seat of the termination of the rectum is usually so thin that the meconium can be distinguished by the dark blue or black colour of the skin; and bulging, becomes plainly visible when the child cries. A central crucial incision should be made with a sharp-pointed bistoury, and the four angles of the integument excised. The aperture must then be maintained by the introduction of an oiled tent or the passage of a bougie daily, until the anus is fully established, which seldom requires more than a week.

*Deficiency of the rectum*, co-existing with imperforate anus, should be managed on the same principle. An incision is made at the site of the anus, exactly in the middle line; and then the dissection must be prolonged cautiously towards the coccyx, extending to the depth of an inch and a quarter. The closed termination of the bowel may thus be reached, or, in the course of a few hours, it comes into view, being forced down by the infant's crying. When reached, the bowel must be opened freely with the bistoury, then drawn down to the external wound, and there attached by sutures. After this procedure, the same precaution will be requisite as before, in order to see that the anus shall become permanently established; a bougie should be passed occasionally for several weeks. In the event of a failure to reach the bowel, colotomy must be performed, in the left iliac region.

*Imperforate rectum*—the anus opening into a cul-de-sac, necessitates similar operative interference. By dilating the cul-de-sac with a sponge-tent, for a few hours, the seat of operation is rendered more perceptible. Then, on introducing the finger into the anal cul-de-sac, if the obstruction is membranous, the termination of the distended rectum can be distinctly felt as a thin septum under the point of the finger. This may be opened by an exploratory puncture with a grooved needle or fine trocar, and if meconium fluid or gas escape, a free aperture should be made with a sharp-pointed bistoury. If the distended end of the bowel cannot be felt, the anal cul-de-sac should be enlarged by an incision, carried towards the coccyx, so as to divide the posterior wall of the sac; and search made in this direction to the depth of an inch and a half or two inches from the anus. Failing to reach the bowel, further operation should be abandoned, and colotomy, in the left iliac region, resorted to.

*Rectal communications* with the bladder, vagina, or perineum—co-existing with imperforate anus, may require operative interference, eventually, to preserve life, as constipation and intestinal dilatation supervene; and in any such case, interference will be justifiable to relieve and render tolerable the otherwise wretched state of existence.

In the case of a communication with the *bladder*, the opening is situated at the neck of the bladder, or more commonly at the anterior part of the prostatic portion of the urethra; it is not usually direct, but through the medium of a narrow channel, and is always small and insufficient. But, the urethral aperture appears to be usually of a valvular character, so that although feces can pass into the urinary canal, the urine is unable to enter the rectum. The same operation should be performed as in the condition of imperforate anus coupled with deficiency of the rectum. Anussat, in 1835, first proposed that the end of the bowel should be brought down and secured to the integumental wound at the site of the anus; a proceeding much advocated by Dieffenbach. A passage lined with mucous membrane is thus made for the escape of the feces, and the liability of feculent extravasation averted, and its consequences, diffuse cellulitis and peritonitis. Colotomy must be had recourse to, when the bowel is seated at a depth beyond an inch and a half to two inches.

Rectal communication with the *vagina*, or a fistulous opening in the *perineum*, may be remedied by either of two operative procedures—enlargement of the original outlet, or the formation of a new anus at the natural site, and closure of the abnormal anus.

Recto-*vaginal* communication has been cured in both ways. Enlargement of the original outlet, first suggested by Vicq-d'Azyr, is effected by division of the posterior wall of the vagina and the perineum as far as the coccyx, and retaining a canula in the bowel. A similar operation was performed by Dr. Barton of Philadelphia, and another by Dr. Parish of the same city. In the one case, the infant was aged nine months, in the other fifteen months. To establish a new passage at the natural site, a curved director or sound should be passed through the recto-vaginal opening into the bowel, with its point directed to the site of the anus; this is then cut up in the middle line, the incision being carried backwards towards the coccyx. A free opening having thus been made in the bowel, it is brought down and secured by sutures to the margin of the integumental wound. Dilatation must subsequently be maintained. Closure of the abnormal communication with the vagina may take place spontaneously; as in a case operated on by Dr. Sharpless of Philadelphia, where the opening closed two months after the substitution of the operation-anus. Generally, it will be necessary to assist contraction and closure by touching the edges with the actual cautery; or, if the opening be large, the edges must be pared and brought together by sutures. After either procedure, the bowels should be kept at rest by opiates, for several days, until closure has taken place.

Recto-*perineal* communication, as the third variety of imperforate anus, has also been treated successfully by both modes of operation. Enlargement of the original outlet is performed by an incision towards the coccyx, and the application of sutures. The results of this procedure were quite satisfactory in two cases operated on by M. Goyrand; one, a male infant, six months old, in whom at the age of sixteen years, defæcation was free and the power of retention complete, even when the

motions were lax; the other, a female, aged eleven months. Equally satisfactory results have been obtained by Mr. Gowlland and by Mr. Curling, in a male, and a female infant, respectively. The formation of a new anus at the natural site has proved successful in the hands of M. Guillon and others. But, enlargement of the original outlet will be preferable in all cases where the opening is sufficiently near the site of the natural anus; this is generally the condition in the female, and sometimes in the male. When, however, the opening is situated beneath the penis, or in the scrotal raphe; the other operative procedure must be resorted to.

The general *result* of unrelieved and long-continued rectal-obstruction, is well shown in a case of imperforate anus with recto-vaginal fistula, operated on by Mr. Lane; the child being four and a half years old. The bowel was opened at the anus, and the septum between the two apertures was divided. Death ensued in twenty-three days. The continual strain upon the rectum had produced distension to a size almost incredible; the rectum and sigmoid flexure of the colon forming an immense reservoir capable of holding five pints of fluid, which occupied the pelvis, the hypogastric, both iliac, and part of the umbilical regions, displacing the viscera upwards and diminishing the cavity of the thorax.

#### FUNCTIONAL DISORDERS OF THE RECTUM AND ANUS.

Under this head may be conveniently noticed certain functional disorders, which are unaccompanied with any structural condition of disease of the part affected, whether the Rectum or Anus. Such are Atony of the Rectum; Irritable Rectum, or Sphincter; Neuralgia of the Rectum, or of the Anus; Pruritus Ani.

*Atony of the Rectum.*—In paraplegia the retentive powers of the rectum and of the sphincter are both lost; but the tonic muscular power of the rectum may itself be deficient, rendering the bowel incapable of thoroughly expelling its contents. Fæcal accumulation is apt to ensue. This occurs in habitual rectal constipation; a state in which the fæces are transmitted through the colon into the rectum, but there lodge.

Besides the ordinary symptoms of constipation; there is also a sense of fulness and weight in the rectum, and severe bearing-down pains occasionally. A mucous discharge resulting from constant irritation, may bring away a little feculent matter from the surface of the mass, and simulate diarrhœa.

The cause of this atonic condition is usually the too frequent and copious use of enemata, a practice more common on the Continent than in this country. French ladies are, I believe, especially subject to the complaint, through the prevalent custom with them more particularly of neglecting the calls of Nature, and then seeking relief by lavements. It occurs also among the enfeebled by age.

The *treatment* of fæcal accumulation in the rectum should be chiefly mechanical. Impacted and indurated fæces may be broken up and scooped out, by means of a lithotomy scoop or a dessert-spoon. Injections, in the first instance, have but little effect in dissolving the accumulation, and generally return immediately; after extraction of the larger lumps, the remainder may be thus removed, and the bowel washed out.

*Irritable Rectum.*—In this functional condition of the rectum, there is frequent and urgent desire to deæcate; analogous to the frequent and urgent desire to micturate, as denoting irritability of the urinary bladder. And the analogy between these two affections holds good still further, in

the common cause of rectal irritability being an unhealthy and irritating state of the fæces, in consequence of gastro-intestinal derangements; just as vesical irritability depends frequently on morbid conditions of the urine. Both affections also depend often on morbid states of the nervous system, and are much influenced by the attention being directed to the part. Various diseases also of the bowel may give rise to its irritability, and in particular, ulcer of the rectum; but the irritability is not then purely functional.

The treatment of rectal irritability must have reference to these diverse causes—whether the state of the alvine evacuations, or of the nervous system, or the associated diseases of the rectum.

Opiate suppositories are most effectual in restraining the distressing inconvenience of an irritable rectum.

Irritability of the *sphincter* alone, is sometimes met with, unaccompanied by any apparent disease of the part. It occurs usually in hysterical females. Pain and difficulty in defæcation are experienced, owing to spasmodic contraction of the sphincter, resisting the expulsive power of the bowel; and when the finger is forced in, it is tightly grasped by the muscle as if girt by a cord. In old-standing irritability, the muscle often becomes hypertrophied, encircling the finger like a thick unyielding ring.

The *treatment* of this affection consists in mild laxative aperients to insure soft motions, and sedative applications. An ointment containing chloroform, opium or belladonna, should be used by means of a grooved-bougie; so that some of the sedative shall reach the mucous membrane lining the internal sphincter which is also occasionally affected. The simple introduction of a bougie appears to afford great relief, when resistance to the evacuation of fæces is considerable. In obstinate cases, and especially when the sphincter has become hypertrophied, a slight incision into the muscle will usually give relief. It should be done on one side, towards the ischium. Constitutional treatment as in other hysterical affections, must be attended to; but often after having failed in every way to overcome this troublesome affection, it ceases spontaneously.

*Neuralgia of the Rectum.*—This affection, unlike irritability, is essentially a painful affection of the rectum, and always unaccompanied by any discoverable disease of the part. The character of the pain is neuralgic, in its being intensely severe, and not excited or aggravated by the action of the bowels or by pressure. But, it is not so distinctly paroxysmal, coming suddenly and after a while disappearing; it is singularly persistent, although varying in intensity at different times; and may continue for years. The pain does not seem referable to any particular spot, extending perhaps up one side of the bowel, as a dull aching pain. This affection of the rectum occurs chiefly in females.

No *treatment* can be designated curative. Sedative applications may have some influence in allaying the pain; opiate suppositories in particular, or the belladonna ointment introduced by a bougie. Constitutional treatment should not be neglected; colchicum and bicarbonate of potash may prove beneficial in a gouty diathesis; or quinine and iron in persons debilitated and worn down by suffering.

*Pruritus Ani.*—Itching at the anus, unconnected with any diseased state of the part, is symptomatic of various causative conditions. Rectal constipation, ascariides, congestion of the mucous membrane, not distinctly hæmorrhoidal, and other disorders of the bowel; are common causes. The complaint may also be sympathetic; as of chronic enlargement of the prostate, or of some uterine or ovarian irritation. Anal itching and

irritation are usually more intolerable at night, depriving the patient of sleep; it is frequently provoked during the day by sitting long upright. Scratching or rubbing the part only aggravates the suffering, and results in excoriation, or the production of a peculiar dry, harsh, and leathery state of the skin, easily disposed to crack.

*Treatment* of this affection consists in removing any exciting cause, and using sedative applications. Hence, it will be imperative to regulate the bowels, and avoid any stimulating condiment, food or drink; or the removal of ascarides may be indicated as the source of irritation; and in any case, absolute cleanliness must be enjoined. Of topical applications; the liquor opii sedativus, chloroform ointment, or vapour, will often prove effectual. The latter may be applied by pouring a little chloroform into a wine-glass which is held to the anus. Mr. Curling highly recommends a lotion composed of a drachm of the sulphuret of potassium and eight ounces of lime-water; the infusion of tobacco with five grains of borax to the ounce, is also very efficacious. In chronic cases, astringent lotions are often beneficial; as lotions of alum, tannin, or the muriated tincture of iron. Counter-irritation, I have found to be singularly remedial, when the anal itching depends on ovarian irritation; a blister applied over the iliac region, on the tender side, has not unfrequently acted as a charm, all other treatment having been quite ineffectual.

## THE GENITO-URINARY ORGANS.

### CHAPTER LVII.

#### INJURIES AND DISEASES OF THE BLADDER—AND URINARY CALCULUS.

THE Genito-Urinary Organs comprise, the kidneys, ureters, bladder, prostate gland, urethra, penis, scrotum, and testis,—in the male; the uterus and ovaries, the vagina and vulva,—the organs of generation in the female. Of these organs, the kidney in respect to its diseases, falls within the allotted province of Medicine, and incidental notice only will be taken of the ureter in this work. But the Student in Surgery must equally study renal diseases as part of the pathology of the urinary system.

The Bladder, lodged within the bony walls of the pelvis, is less liable than many other organs to external Injury, as wounds or rupture; and only occasionally, to the intrusion of foreign bodies from without, through the urethra or by gunshot penetration; but it is very commonly the receptacle of urinary concretions or Calculi, and it is subject to various Diseases, principally inflammation and morbid growths or tumours. This organ is also specially prone to Functional Disorders; *e.g.*, irritability of the bladder, arising from numerous causes, local and constitutional.

These lesions, diseases, and disorders, severally demand the attention of the Surgeon, in regard to their special pathology and treatment.

*INJURIES.*—*Laceration* of the bladder occurs not unfrequently with fracture of the pelvis, this additional injury being a most serious complication in consequence of the extravasation of urine. An open wound, as by a bullet, may allow the urine to escape freely, externally; and recovery has then been known to ensue. Several such cases are related by Guthrie,

and by Thomson as having occurred at the battle of Waterloo. *Rupture* of the bladder is also not very uncommon, as the result of blows, kicks, or contusions on the lower part of the abdomen; especially when the bladder is fully distended and rises above the pubes in contact with the abdominal wall. Thus, this accident may occur from a fall in wrestling, the uppermost man coming down upon his antagonist; or from running against a post in the dark, an instance of which is related by Liston. In that case, a large calculus which occupied the bladder, was shattered into fragments by the concussion.

The *effects* of laceration or rupture of the bladder vary according to the seat of injury, as above or below the reflection of the peritoneum; whereby extravasation of urine takes place into the peritoneal cavity, or into the cellular tissue of the pelvis. In the one condition, fatal peritonitis speedily ensues; in the other, diffuse inflammation is followed by sloughing of the cellular texture of the pelvis and abdominal wall as infiltration proceeds, and a less speedy termination.

The *symptoms* of ruptured bladder are obvious; sudden and intense burning pain, in the hypogastric region, with immediate collapse, and inability to pass water or a little bloody urine coming away through the urethra. On introducing a catheter, the bladder is found to be empty, or a small quantity of bloody urine is drawn off. In gunshot wound implicating the bladder, the urine may perhaps be seen to escape through the track of the wound.

*Treatment.*—Extravasation should be immediately prevented extending further, by the introduction of a full-sized gum-elastic catheter into the bladder; which is retained by means of tapes, that the urine may dribble away as fast as it descends into the bladder. Any appearance of extravasation presenting externally, must be at once met by free incisions; so that the infiltrated fluid may escape, and sloughs as they form. By this prompt prevention of further extravasation and arrest of the diffusive inflammation in the cellular texture, a circumscribing barrier of lymph may be thrown out, and life be preserved. Peritonitis, consequent on extravasation into the peritoneal cavity, may also be diminished by using the catheter as directed, but the fluid already imprisoned within the peritoneum will still maintain the inflammation. The general treatment consists in the administration of opium and stimulants, with whatever nourishing food can be taken to support the patient through the subsequent exhaustion, especially in the process of sloughing.

*Rupture of Ureter.*—This rare form of injury has been known to happen from external violence, and recovery in one instance at least. In a case which Mr. Stanley has recorded, a large accumulation of fluid formed around the seat of injury, with considerable circumscribed swelling and fluctuation, which was repeatedly tapped. Ruptured pelvis of the kidney, in another case, led to the formation of a similar cystic collection of urine behind the peritoneum; and no less than six pints of urine were drawn off by tapping, at one sitting. Death occurred about ten weeks after the accident.

*Foreign Bodies.*—Various foreign bodies, such as portions of catheters, or bits of pencil or tobacco-pipe, are occasionally thrust into the bladder, through the urethra. Any substance thus introduced, is usually of some length, and lying perhaps across the bladder, is rarely expelled in passing water; it must therefore be extracted surgically. This may sometimes be done with a lithotrite, by catching the body in the direction of its long

axis, or by crushing the substance as a stone; but sometimes it has been found necessary to have recourse to the operation of lithotomy. Knowing the size and shape of the foreign body, the median operation can be more frequently selected. Bullets, bits of clothing or other bodies, are occasionally lodged in the bladder by gunshot wound, implicating this organ. Any such body must be removed in like manner. In fifteen cases, which Mr. Dixon has collected, the ball had entered the bladder, either primarily, or in consequence of abscess and ulceration after having lodged near this organ; and in ten of these cases, the ball was removed by the operation of lithotomy, with successful results. Of the remaining five cases, the termination is not recorded.

In all cases, a foreign body in the bladder soon becomes encrusted with urinary deposit; and by thus increasing the difficulty of its extraction, and as a persistent source of irritation, inducing an unhealthy state of the bladder, the result of any operative procedure might be unsuccessful.

### URINARY CALCULUS.

Urinary Calculus, or stone, signifies a concretion of one or more of the constituents of the urine, forming a hard mass.

*Origin.*—It originates from the precipitation of urinary constituents, as Urinary Deposits,\* in consequence of a loss of solvent capacity in the water of the urine. This may arise in one of three ways; by an excess of any substance for the water to dissolve, by a deficiency of water for solution of the substance; or by the presence, or absence, of some third substance. In either way, different natural analyses of the urine occur: precipitating urinary deposits and resulting in the formation of urinary calculi.

*Production.*—The deposit may aggregate from a focus of its own substance, more frequently it gathers around a foreign body as a distinct nucleus; in either way producing a calculus. In the former mode of production, aggregation is due; either, to an excess of insoluble constituents and thence their immediate precipitation, as in the ordinary forms of uric acid, urate, and oxalate concretions; or, to stagnation of the urine in the bladder,—in consequence of paralysis, chronic inflammation and hypertrophy of the organ, enlargement of the prostate, or stricture of the urethra, all of which conditions severally lead to the retention of urine, and perhaps affect its chemical constitution,—as in the formation of phosphatic calculi. When a calculus forms around a distinct nucleus, this is some foreign body; either a small clot of blood or mucus derived from the urinary organ in which the calculus originated, or it may be some small foreign body introduced from without into the bladder through the urethra, or by wound or ulceration of the organ.

The constituents of a calculus are held together by some kind of cement, which is believed to be animal matter; mucus, fibrin, or fatty matter; or it is said, possibly blood, epithelium, or even pus.

The *seat* of origin in the urinary organs, may be either the kidney or the bladder, and thence a calculus is designated *renal* or *vesical*; usually it originates in the kidney, and subsequently descends as a small stone into the bladder, where it increases by further concretion.

Urinary calculus differs in its physical characters, and chemical composition; thus representing different classes and species of Urinary Calculi.

\* The reader will find a "Practical View of Urinary Pathology and Deposits," in the second edition of the Author's work on the Irritable Bladder, its Causes and Treatment.

*Physical Characters.*—Urinary Calculus varies in point of size, shape, weight, colour, odour, consistence, structure on section, and number. The *size*, is extremely variable; from that of a hemp-seed, pea, nut, or almond, to a cricket-ball and occupying the whole cavity of the thickened bladder. Of such large-sized calculi, one may be seen in the Museum of the Royal College of Surgeons, and another in the valuable collection of the Norfolk and Norwich Hospital Museum. That in the College collection measures 16 inches around its long axis, and 14 inches around its short axis; it weighs 44 ounces. An unsuccessful attempt was made by Mr. Clive to remove it from Sir Walter Ogilvie, who died on the tenth day. A nearly similar sized stone was removed by Uytterhoeven of Brussels, by the high operation. Phosphatic calculi usually attain the largest size. The *shape* also varies remarkably, and principally according to the situation and composition of the stone. Renal calculus is irregular, and often moulded to the form of the calices and pelvis of the kidney; in the ureter, a stone is generally cylindrical; the vesical is more uniformly of a flattened ovoid shape, or globular; while the prostatic is pear-shaped or singularly faceted. In relation to composition; uric acid and urate of ammonia calculi are usually smooth and regular; the oxalates tuberculated like a mulberry,—hence the common name of this calculus; the phosphatic, may be smooth and regular, or irregularly contorted. Many other forms are met with, which being readily recognised, need not be specified. The *weight* depends more on the composition than the size of the stone; the phosphatic being very light, the oxalates very heavy, and uric acid or urates between the two. The average weight is an ounce; but extremes have been met with; in a stone of 10 grs. taken from a boy; another of nearly 6 ounces, removed by Sir A. Cooper, and another of 32 ounces, in the Museum of Trinity College, Cambridge. Of heavy calculi not removed, Deschamps saw one that weighed 51 ounces; and Morand, one weighing 6 lbs.—the heaviest on record. The *colour* of a calculus represents only the chemical nature of the surface or external crust of deposit; the interior is often very different. A white surface signifies a phosphatic crust; a cinder-gray, that of urate of ammonia; a yellow pale brown, or brown, the uric acid; cinnamon-brown, the uric or xanthic oxide; a mahogany brown, brownish or blackish green, the oxalate of lime; a gray-greenish or slate colour, the cystic oxide. The *odour* of a recently extracted calculus is sometimes peculiar. Phosphatic calculus may be ammoniacal, and oxalate of lime, on section, is said to emit a faint odour of semen. An aromatic smell, as of castor or musk, is sometimes perceptible. The *consistence* varies from that of mortar or sand to that of granite. But this will depend on the chemical nature of the calculus and on the intermixture of organic matter, or moisture in a recently extracted stone. Phosphatic calculus is generally soft; the uric acid hard; and the oxalates, very hard. The crust is usually softer than the interior, and the nucleus has the densest consistence. A rapidly formed stone is softer than one of slow production.

*Structure.*—On *section*, a calculus generally presents a nucleus, and the surrounding concretion, which has a more or less distinct external crust. The colour and consistence of the section may be uniform, when the stone consists of only one chemical constituent,—forming a *simple* calculus; or it varies in appearance at different depths, when consisting of different elements,—forming a *compound* calculus. The disposition of the concrete matter may be continuous,—presenting no visible arrangement; but usu-

ally it is deposited in concentric layers or laminæ, and sometimes lines radiate from the centre to the circumference of the stone. Varnishing the dried surface will exhibit its appearance most distinctly. This laminated arrangement, corresponds apparently to the successively active periods of urinary deposit. Such is Prout's explanation; and it would seem therefore, that a continuous concretion must be due to an uninterrupted deposit. Lamination may occur in the formation of both a simple and a compound calculus. It depends apparently on varying states of the urine. When some length of period intervenes in the deposition of matter, the surface of the concretion becomes water-worn, and worm-eaten; fresh deposition is less firmly adherent, and consequently a calculus thus constructed is disposed, when broken, to split into its concentric laminæ. In compound calculus, the successive deposition of different matter may be in a regular alternation. The *nucleus* is situated usually in or near the centre of the calculus; sometimes it is very eccentric, as in some renal concretions. Occasionally, more than one, or possibly several nuclei may be found, as distinct centres of concentric deposition. More rarely, the nucleus is loose within the substance of the calculus; owing apparently to a layer of blood or mucus having gathered around the nucleus, and then the concretion taking place on this layer. When the organic matter dries and pulverizes, the nucleus is left loose in the stone. Lastly, the nucleus may have disappeared, leaving a central cavity; a result probably of the nucleus itself having been blood or mucus, which has disappeared.

The *number* of calculi varies chiefly according to the seat of the stone. In the bladder, usually there is only one; in the kidney, two or more; and in the prostate, several. Vesical calculi are, however, sometimes numerous; two to six or eight are not very uncommon; and instances are on record of 117; 142 about the size of marbles, were removed by Sir A. Cooper; 307, 678, and even 1000 have been found; the latter number having been extracted by Dr. Physick from an American Judge. This number is the largest on record; the stones varied in size from partridge shot to a bean.

*Chemical Composition.*—In regard to their essential constituents, urinary calculi, like deposits, may be divided into two classes; a third class represents the more rare forms. (1) Calculi consisting of uric acid and the urate of ammonia; with their varieties, the oxalate of lime, uric or xanthic oxide, and cystic oxide or cystine; (2) phosphatic calculi, in all their varieties, as phosphate of ammonia and magnesia, phosphate of lime, and mixed phosphates of lime, magnesia and ammonia,—constituting the fusible calculus; (3) the fibrinous uro-stealth, carbonate of lime, and silicious calculi.

The *relative frequency* of different Calculi varies in different countries. Dr. H. V. Carter's observations, on the composition of more than 100 specimens in the Grant Medical College, Bombay, show the relative frequency of the different urinary constituents, as forming the nucleus and the body of calculi, in India and in England. (1) That in Bombay, the proportion of calculi having oxalate of lime for their nucleus, or wholly composed of it, is about twice as great as in England; taking for comparison certain standard collections of calculi in this country. (2) That the proportion of calculi having uric acid or a urate for their nucleus or entire substance, is considerably less in India than in England; in the former country, urate of ammonia calculi are somewhat more frequent than uric

acid calculi, and conversely in England. (3) That the number of calculi wholly composed of earthy phosphates, or having them for a nucleus, is proportionately much fewer in India than in England, owing chiefly to the rarity of the mixed phosphate in the former country.

Urinary calculi may be severally *distinguished* both by their physical characters, and by chemical tests; sometimes also by the crystalline forms of their constituents, as shown by microscopical examination.

Physical properties are most readily recognised, but they are least definite and distinctive; Calculi will, therefore, be described in the order of their chemical affinity, with regard to *Tests*.

*Uric, or Lithic Acid Calculus.*—The most common of all calculi, is that consisting of lithic acid. It was discovered by Scheele in 1776. Its colour is generally light brown, varying however from pale brown to dark brown; and sometimes whitish on the surface, owing to its having become coated with amorphous urate of ammonia or with phosphate of lime. The shape is usually ovoid, and somewhat flattened; the surface smooth, or beset with small tubercles, so as to resemble the surface of oxalate of lime-calculus; the size varies from that of a pea to an orange; and its consistence is hard in proportion to the purity of the calculus; sometimes emitting a ringing sound on percussion, and breaking up into sharp angular fragments. The calculus is composed of concentric laminae, and presents lines or fibres radiating from the centre to the circumference of the stone; both these appearances are marked in proportion to the purity of the calculus, and determine the lines of fracture when the stone is broken. The nucleus may be quite white, although consisting of pure uric acid; owing, as Dr. G. O. Rees has shown, to the absence of colouring matter. The fracture is crystalline. *Tests*:—Combustible, and destroyed by heat; turned red by nitric acid, forming a murexide; soluble in carbonate of potash, evolving *no ammonia*.

(2) *Urate of Ammonia Calculus.*—This is not a common form of calculus, urate of ammonia being soluble in warm urine; and it is generally confined to children. It was discovered by Fourcroy and Vauquelin in 1798. The colour of this calculus is that of clay or slate, and pretty characteristic, but less so when inclining to red or brown; it has an ovoid shape, and a smooth or slightly tuberculated surface, and is of small size; the section is homogeneous, seldom presenting a distinctly concentric laminated condition. Fracture is earthy,—not crystalline. *Tests*:—Combustible, and destroyed by heat; turned red by nitric acid, forming a murexide: soluble in carbonate of potash, evolving *ammonia*.

Urates of *Soda* or *Lime* are not found as calculi; these urates are mixed with urate of ammonia or uric acid in compound calculi.

(3) *Uric or Xanthic Oxide.*—A very rare calculus, four specimens only having been recorded. It was discovered by Dr. Marcet in 1815. The calculus has a cinnamon colour, a somewhat flattened shape and small size,—resembling a flattened pullet's egg, in a stone examined by Stromeier; its texture is hard and laminated. Fracture, not crystalline. Uric oxide bears a close relation to uric acid, and results apparently from an imperfect oxidation of the chemical material which forms uric acid. *Tests*:—Combustible, and destroyed by heat, but not turned red by nitric acid; soluble in ammonia, *not* crystallizing when evaporated; insoluble in carbonate of potash.

*Cystic Oxide, or Cystine Calculus.*—This also is a rare calculus,

discovered by Wollaston in 1810. It has a yellowish-brown colour, approaching that of the uric acid calculus, but after long exposure, it changes to a peculiar gray-greenish or slate colour; there is also a characteristic waxy, glistening, and slightly transparent appearance. Rounded and smooth or tuberculated, and of small size, the consistence is soft and pulverescent; a section exhibits no tendency to concentric laminae, and only very imperfect radiation. The fracture is crystalline; powder scraped with a knife is perfectly white, whether the stone be brown or green. Hereditary disposition to the formation of this calculus is strongly evinced; in 22 cases, 10 occurred in four families, and in 3 cases, the subjects were brothers. Cystic oxide calculus differs from all others chemically, in containing a large proportion of sulphur—about 26 per cent. It originates in the kidney, and not in the bladder as its name might imply. *Tests*:—Combustible, and destroyed by heat, but not turned red by nitric acid; soluble in ammonia, crystallizing when evaporated in six-sided plates; soluble in strong caustic potash.

(5) *Fibrinous Calculus*.—Described by Dr. Marcet and Dr. Prout; this rare calculus so called, seems to have occurred in the form of pea-shaped bodies, of a yellow colour, and consisting of dried, coagulated albuminous matter. It can scarcely be regarded as a concretion;—although such masses have presented considerable lustre and a vitreous fracture; resembling yellow wax in appearance. *Tests*:—It may be distinguished from cystine, by being soluble with difficulty, in ammonia, and not crystallizing when evaporated.

(6) *Uro-Stealth Calculus*.—Another very rare pseudo-form of calculus, consisting of resin or fatty matter. It was originally described by Heller in 1844; several small bodies of this kind having been passed by a man, aged twenty-four, who suffered from symptoms of stone. Since that time, Dr. Moore of Dublin has examined several specimens sent to him by Dr. Robert Adams. *Tests*:—Soluble in ether and caustic potash; insoluble in boiling water and nearly so in alcohol; when heated and melted, the odour of benzoin is emitted.

(7) *Blood-Calculus*, consists apparently of disintegrated blood-corpuscles associated with phosphate of lime; it therefore represents another form of pseudo-calculus, and which is also very rare. Described by Dr. Alison, and examined by Dr. G. O. Rees; a few such calculi were found in the pelvis of the kidney of a man who died of consumption. They had a black colour, and ranged in size from a coriander-seed to a small horse-bean; they were friable, and the fractured surface presented an amorphous, dark rusty appearance. *Tests* seem to have elicited nothing peculiar; the calculus matter was partly combustible, and soluble in liquor potassæ.

(8) *Carbonate of Lime Calculus*.—An extremely rare form of calculus, discovered by Brugnattelli in 1819. Of a perfectly white or an ash colour, spherical or irregular, and varying in size from a pea to a nut or larger; the consistence is usually soft and friable, but sometimes very hard. Section shows no concentric laminae or only an imperfect lamellar structure. The texture is amorphous. Prostatic calculi consist almost entirely of carbonate of lime, as Dr. Thudichum has shown; but it is always doubtful whether the lime or the carbonic acid were in any case derived from the urine. *Tests*:—Not combustible, and not destroyed by heat; soluble with hydrochloric acid, effervesces *before* heating; soluble in acid, when neutralized, gives a precipitate with carbonated alkalies and oxalate of ammonia.

(9) *Oxalate of Lime Calculus*.—This is the next most common after the uric acid calculus. It was discovered by Wollaston in 1797, but the nature of oxalic acid deposit was long afterwards originally investigated by Dr. Golding Bird. The colour is rich mahogany brown, or sometimes blackish-green; the shape spheroidal, and surface tuberculated, angular, or even spinous, rarely perfectly smooth; and varying in size from a marble to a horse-chestnut. This remarkable colour and external appearance, have given the special name “mulberry” to the oxalate of lime calculus. Its density and weight are great; and section shows an imperfectly laminated structure of irregular waved lines, often resembling knotted heart of oak; occasionally,—a notably radiated appearance, like a series of minute needles placed side by side. The fracture is crystalline. Dr. Lionel Beale has specially traced the formation of this calculus, from an oxalate of lime concretion not larger than 1-500th of an inch; and he finds that dumb-bell crystals are first aggregated together into a small collection, in the interstices of which crystalline matter is deposited, forming a microscopic calculus.

Varieties of appearance are produced by the deposition of crystallized oxalate of lime on the surface of the calculus; sometimes as a coating of transparent octahedrons, or it may be opaque; and the calculus looks as if studded with pearl-spar. The deposition also of amorphous matter, as urates or phosphates may fill up the intervals between the tubercles or spines, and give the whole an ovoid shape. In compound calculi, oxalate of lime deposition presents the beautiful appearance of fortification agate.

Rarer *varieties* are occasionally met with. The small, smooth, globular “hemp-seed” calculus, of a light brown colour. Also, the calculus, of a white or pale brown colour, and crystalline throughout. Lastly, the pure white oxalate of lime calculus. These varieties are generally found in the kidney. *Tests*:—Not combustible, and not destroyed by heat; soluble with hydrochloric acid, effervesces *after* heating; solution in acid, when neutralized, gives a precipitate with carbonated alkalies and oxalate of ammonia.

(10) *Phosphate of Ammonia and Magnesia*—or *Triple Phosphate*.—Discovered by Wollaston in 1797, this calculus is not common. It is of a white or gray colour, irregular shape and somewhat spiculated, may attain a large size, and has a friable consistence; is imperfectly laminated, and the fracture sometimes crystalline like alabaster. *Tests*:—Not combustible, and not destroyed by heat; soluble with hydrochloric acid, but does *not* effervesce either *before* or *after* heating; solution in acid, with excess of ammonia, gives a crystalline precipitate.

(11) *Phosphate of Lime Calculus*—also discovered by Wollaston in 1797, is rarely found in the bladder uncombined with other salts; and it seldom forms the nucleus of other calculi. It has a pale brown colour; spheroidal form and smooth surface; is usually small, friable, and laminated. This condition of the calculus is of renal origin, and consists of the neutral phosphate of lime. Another condition is of vesical origin, and consists of bone-earth phosphate; it occurs in the shape of irregular masses resembling mortar, or a granular semi-crystalline powder, enveloped in a tenacious mucus. Phosphates form around other calculi, or foreign bodies; but they are scarcely ever succeeded by a deposit of uric acid or urate of ammonia, or of oxalate of lime. *Tests*:—Not combustible, and not destroyed by heat; soluble with hydrochloric acid, but does *not* effervesce either *before* or *after* heating; solution in acid, with excess of ammonia, gives an amorphous precipitate.

(12) *Phosphate of lime, and phosphate of magnesia and ammonia calculus—or the Mixed Phosphates—Fusible Calculus.*—Another discovery by Wollaston in 1797, this is the most common of the three phosphatic calculi, and represents rather more than 1 in 12 of all calculi. The calculus is of a white, gray, or dull yellow colour; generally of a very irregular shape, and moulds itself to the situation where found; sometimes globular or ovoid, sometimes in many pieces and assuming a cubic or tetrahedral form. It may attain a considerable size, and has a very friable consistence and pulverescent character, or a soft consistence, resembling moist chalk. Section shows generally a concentric lamellar structure, and sometimes shining crystals of the triple phosphate between the laminæ, or a semi-crystalline appearance. The relative proportion of the constituent phosphates varies exceedingly, and the predominance of one or the other phosphate gives peculiar characters; an abundance of triple phosphate presents a crystalline texture, while that of phosphate of lime exhibits an amorphous earthy appearance. Mixed phosphates are more commonly deposited on foreign bodies introduced into the bladder; encrusting them with white friable calculus masses. *Tests*:—Not combustible, and not destroyed by heat; soluble with hydrochloric acid, but does *not* effervesce either *before* or *after* heating; solution in acid, with excess of ammonia gives a white, partly crystalline, partly amorphous, precipitate; without addition easily *fusible* before the blow-pipe.

(13) *Silicious calculus.*—As a separate concretion this calculus has not been met with; but silica has been found in other calculi by Berzelius, Vauquelin, Fourcroy, and Venables. *Tests*:—Silica is negative with regard to all the tests for other concretions; it is *not* acted on, by heat, acids, or alkalies.

The relations of *all* these Calculi to *Tests*, as already stated with reference to the several forms of Calculi, and moreover, the additional tests pertaining to *each*, are conveniently shown in the following tabular view of General and Special Tests for Urinary Calculi; which represents also the order of chemical examination. It is enlarged, from the well-known Lectures of Dr. Bence Jones on Animal Chemistry.

The *appliances* requisite for the *examination* of Calculi are few and simple; a platinum spoon or piece of platinum foil, a spirit-lamp, and sometimes the aid of a blow-pipe; test-tubes and watch-glasses, with the acids,—nitric and hydrochloric, and the alkalies,—carbonate of potash and oxalate of ammonia. Certain special reagents will be noticed in the table.

The *order of procedure* is, first to test a bit of the calculus in powder, by *heat*, and thus refer it to one of the two divisions; calculi combustible, and destroyed by heat, leaving only a very little residue; or, calculi non-combustible, and not destroyed by heat, leaving a considerable residue. In the former case, the original powder is to be tested for uric acid, urate of ammonia, uric-oxide, or cystic-oxide; in the latter case, it is to be tested for (carbonate of lime), oxalate of lime, ammoniaco-magnesian, or triple, phosphate, phosphate of lime, or mixed phosphates. Next, the *mineral acid* test is to be applied; if a combustible calculus, dilute nitric acid should be used; if a non-combustible calculus, dilute hydrochloric acid is preferable. Then, the *alkaline* test must be applied. Lastly, the *special tests* may be resorted to.

*Causes of Urinary Calculi.*—The urinary formation of calculi has already been adverted to. But certain *predisposing* causes seem to have a tendency to the production of stone.

## Table for Examining Urinary Calculi.

1. By Heat.	2. By Acids.	3. By Alkalies.	Nature of the Calculus.	Special Tests.
Destroyed by Heat.	{ With nitric acid, red.    }	{ Soluble in carbonate of potash, evolving no ammonia. }	Uric acid.	{ Solution in caustic ammonia or potash, on the addition of an excess of acid, crystallizes in angular crystals. Not soluble in water. }
		{ Soluble in carbonate of potash, evolving ammonia. }	Urate of ammonia.	{ Soluble in water, when boiled. Solution in water, with a few drops of ammonia, evaporated, crystallizes in needles—microscopic. }
		{ Soluble in ammonia, not crystallizing when evaporated. }	Uric or xanthic oxide.	{ Insoluble in carbonate of potash; dissolves without effervescing in nitric acid, leaving a lemon-coloured residue; soluble in strong sulphuric acid, not precipitated by dilution. }
		{ Soluble in ammonia, crystallizing when evaporated. }	Cystic oxide or cystine.	{ Soluble in strong caustic potash; the solution, boiled for a few moments, on the addition of a drop of dilute acetate of lead, gives sulphuret of lead. }
		{ Soluble in ammonia with difficulty, not crystallizing. }	Fibrin.	{ With nitric acid becomes directly yellow. Solution in caustic potash precipitable by acetic acid in amorphous form. }
Not destroyed by heat.	{ With hydrochloric acid soluble; before heating effervesces. }	{ Solution in acid, when neutralized, gives a precipitate with carbonated alkalies and oxalate of ammonia. }	Carbonate of lime.	Soluble in dilute acetic acid, with effervescence.
		{ Solution in acid, when neutralized, gives a precipitate with carbonated alkalies and oxalate of ammonia. }	Oxalate of lime.	{ Insoluble in acetic acid. Boiled with carbonate of soda, oxalate of soda is dissolved, precipitated by chloride of calcium. }
		{ Solution in acid, with excess of ammonia, gives a crystalline precipitate. }	Phosphate of ammonia and magnesia.	{ With half its bulk of phosphate of lime (bone-earth), is very fusible before the blow-pipe. }
(Not destroyed by heat.)	{ (With hydrochloric acid soluble; does not effervesce before or after heating.) }	{ Solution in acid, with excess of ammonia, gives an amorphous precipitate. }	Phosphate of lime.	{ With twice its bulk of phosphate of ammonia and magnesia, is very fusible before the blow-pipe. }
—	—	{ Solution in acid, with excess of ammonia, gives a white, partly crystalline, partly amorphous precipitate. }	Mixed phosphates.	Without addition, easily fusible before the blow-pipe.
Not acted on.	Not acted on.	Not acted on.	Silica.	{ Fused with twice its bulk of carbonate of soda, forms glass, soluble in water, precipitable by hydrochloric acid. }

*Climate and Locality* have apparently some predisposing influence. Calculus is more common in temperate than in warm and cold regions, and more especially in humid countries of moderate and changeable temperature, such as Holland, France, Germany, and England. It occurs, however, very frequently in Egypt, Isle of France, Russia, Bagdad, and both the East and West Indies. Some parts of the same country are certainly more prone to calculus-production than other parts; as particularly the county of Norfolk in this country. *Race*, it is said, has different proclivities; that calculous disorders are more common among white than dark races of men, yet stone is of very frequent occurrence among the natives of India.

*Hereditary* transmission is evinced in the gouty diathesis, and the production of lithic acid calculi.

*Sex* undoubtedly affects the relative proportion; stone is less frequent in females than males, in the proportion of 1 to 20, or 1 to 23. This remarkable disproportion is attributed mainly to the peculiar anatomical disposition of the female urethra; its comparative shortness, larger size, dilatability, and straight course, all these circumstances facilitating the passage of a small stone.

*Period of life or Age.*—Stone may occur at any age, and according to Stahl and Geyer, it occasionally exists as an intra-uterine affection. But the two extremes of life seem to be most subject; stone being met with most frequently, it is said, in young and in old people. Of 5376 cases collected by Civiale; 1946 occurred before the age of 10 years, 943 from 10 to 20, 460 from 20 to 30, 330 from 30 to 40, 391 from 40 to 50, 513 from 50 to 60, 577 from 60 to 70, 199 from 70 to 80, and 17 after 80 years of age. Coulson has collected 3264 cases of lithotomy; under 20 years of age, the proportion was 71·20 per cent.; between 21 and 40 years, 12·10 per cent.; between 41 and 60, 10·87 per cent.; and between 61 and 80, 5·72 per cent. Sir H. Thompson's table comprises 1827 cases; under 20 years of age, 60·42 per cent.; between 21 and 40, 10·18 per cent.; between 41 and 60, 17·56 per cent.; and between 61 and 81, 11·83 per cent. Respecting the value of these statistics, Mr. Coulson has well remarked, that they represent the absolute number of persons affected with stone, at different ages; but not as relative to the total number of persons living at the several periods of life. Thus, if all persons under 20 years were affected with a certain disease, and all persons over 70 years were affected with the same disease; the liability would be the same, although the absolute number of persons attacked would be very different. By correcting this error between absolute and relative numbers, the tables would show that children and young persons are less liable to calculous disorders than is commonly supposed; that from 20 years upwards, the tendency goes on increasing in a very remarkable manner to the end of life. Sir H. Thompson thus expresses it; "that the proportion of elderly calculous patients to the existing population at their own ages, is larger than the proportion of children affected is to the number of existing children."

*Habits of life* have unquestionably some causative tendency. Thus, sedentary habits diminish the perspiratory secretion, and throw increased work on the kidneys; high living and especially indulgence in various kinds of nitrogenized food, and certain beverages, supply the material for uric acid and other allied concretions; while indigestion and secondary mal-assimilation in the textures, generate uric acid. All this pathology

of Urinary Deposits, is fully considered in my Treatise on the "Irritable Bladder."

Various morbid conditions of the *urinary organs* may induce calculous formations; the presence of a foreign body especially, which solicits the precipitation and deposition of the urinary constituents around itself as a nucleus.

Other accredited causes are doubtful. Thus, the imputed influence of certain mineral waters is fallacious, none of the forms of calculi corresponding to the salts in such waters. The alleged exemption of persons in certain occupations, as soldiers and sailors, seems very doubtful.

**RENAL CALCULUS.**—A stone forming in the pelvis of the kidney may, or may not, be attended with pain or other symptoms of nephritic irritation. Frequently it remains quiescent and unsuspected when lodged in this dilated portion of the ureter. It may there attain a large size and remarkably irregular shape, being moulded to the pelvis and calices of the ureter within the hilus of the kidney. Absorption of the kidney-substance results from the continued pressure, and this is attended with pain in the lumbar region and symptoms of nephritis. In rare cases, abscess has been known to ensue and the stone discharged through an aperture in the loin.

A *small* stone in the pelvis of the kidney usually descends through the ureter into the bladder; it gradually increases in size, as a vesical calculus, by accumulating concretion on its surface.

The *descent* or passage of a renal calculus is accompanied with more or less severe pain and constitutional disturbance, in proportion to the size and shape of the stone. A small, smooth stone, may descend without occasioning any notable suffering. A larger-sized, and rough stone, as a mulberry calculus, descends with much difficulty and causes proportionate agony. After perhaps some symptoms of nephritic irritation, the patient is seized with sudden and excruciating pain in the loin, extending down the course of the spermatic cord to the testicle,—which is often retracted, and down the thighs. This agony may, as it is said, "double the patient up," and make him roll on the ground, vainly seeking and imploring relief. It is worse to bear, and to witness, than the pain in passing a gall-stone. Bloody-urine, vesical irritability and frequent micturition, with vomiting and constitutional irritation, are the additional symptoms of a descending renal calculus, and which simulate acute nephritis. But the constitutional disturbance is not febrile, the pulse remaining comparatively unaffected. These symptoms continue, with occasional remissions, from generally, twelve to twenty-four hours,—the usual period occupied by the descent of a renal calculus; when, on its entering the bladder, all the symptoms suddenly cease. This origin, course and character, and termination of the symptoms, determine the diagnosis. Sometimes, the calculus remains impacted in the ureter, and symptoms of calculous pyelitis supervene. When the stone has become vesical, and is lodged in the bladder; the symptoms of stone in the bladder ensue.

**Treatment.**—Only palliative measures are available. Opium is the most efficacious anodyne for assuaging the nephralgic pain, and the patient can be kept under its influence during the whole period of passing the stone. Chloroform may, however, be administered with advantage, from time to time as a relaxant. The warm bath is also a most serviceable adjunct. Cupping in the loins, followed by warm fomentations, may afford some relief. The bowels should be thoroughly emptied by mild oleaginous enemata,—and diluent drinks freely allowed.

STONE IN THE BLADDER.—*Symptoms*.—A stone, *loose* in the cavity of the bladder, falls into the most dependent part, behind the prostate; but it shifts about according to the varying posture of the patient. The symptoms produced, arise from the mechanical irritation and the obstruction caused by the stone as a foreign body in the bladder. They are always essentially the same in kind, though modified in degree in different cases, and may be comprised under four heads; pain, chiefly in the glans penis; irritability of the bladder with increased frequency of micturition; obstruction occasionally to the passage of urine; and morbid conditions of the urine, bloody urine in particular. In addition to these four symptoms, which severally may arise from other causes than stone; there is the physical sign of a hard body elicited by *sounding* the bladder with a metallic instrument, whereby a stone can be felt and heard when struck,—the sensation and sound as of stone being transmitted through a metallic instrument to the hand and ear. This touchstone, as to the presence of a calculus, is conclusive, when available; and it alone is far more diagnostic of stone than all the mere functional symptoms of its presence.

Taking these symptoms in the order mentioned, their respective characters must be noticed more particularly. The *pain* is that of a dull weight about the neck of the bladder, and perhaps an uneasy sensation extending to the lower part of the abdomen, the perineum, or thighs, or even to more remote parts, as the knee, heel, foot, or arm; but the pain shoots along the penis and centres in the *glans*. Here the pain is more acute, and it is aggravated *after* each act of micturition, when the stone settles down on the more sensitive trigone vesicale of the bladder behind the prostate. In consequence of this pain in the glans penis, children acquire the habit of constantly handling and pulling the prepuce, whereby it becomes conspicuously enlarged and elongated; the recumbent position also is often sought instinctively in passing water, to relieve the recurring attack of suffering. The *vesical irritability* and frequent desire to evacuate the bladder, are in like manner aggravated *after* micturition; for as the urine is strained off by an urgent effort, the stone settles down on its sensitive bed. Thence micturition is not unfrequently spasmodic and involuntary. The semen may be ejected at the same time, and sometimes with troublesome priapism; and there is a tendency to prolapsus of the rectum, in consequence of the oft repeated straining and spasmodic efforts to relieve the bladder. When the bladder is empty, any movement of the body will be more or less communicated to the stone, which rolls about with every change of posture. Personal experience soon restrains the sufferer's movements. Exercise is avoided, and he shuns any sudden or violent exertion; the pain is increased also by any jolting motion, as in jumping, riding, or driving. The *urine*, passed frequently and in small quantities at a time, may flow freely, in a full stream; but it is ever liable to *stop abruptly*, owing to the stone being washed forward suddenly against the neck of the bladder, thus closing the urethral orifice. The *character* of the urine changes. It becomes clouded and sometimes loaded with mucous or muco-purulent deposit, which may clear off as the bladder gets reconciled to the presence of a stone. But it is more often and characteristically tinged or streaked with blood, sometimes amounting to vesical hæmorrhage; and this symptom may continue for a long period. *After* micturition or any rough exercise, bloody urine is more apt to occur, from attrition of the stone and interior of the bladder.

*Sounding the Bladder*.—A *sound* is a solid steel instrument, shaped

like a catheter; but with a shorter curve, and having a bulbous extremity and a broad, flat smooth handle (Fig. 429). It should be smaller than a full-sized catheter, this reduction and its shorter curve enabling the instrument to be freely turned about in the bladder; while its somewhat enlarged extremity may aid in detecting the stone, and its expanded

FIG. 429.

handle render the sensation communicated more perceptible to the touch. A proportionately smaller instrument, and with an abrupt curve, will be suitable for children, in whom the bladder is situated higher up in the pelvis than in adults. Sounds of various sizes and curvature will be required for different cases.

FIG. 430.

Sounding is performed in the following manner:—The bladder containing three or four ounces of urine, or having been distended to that amount by injection with warm water, and the patient lying in the semi-recumbent position; the instrument is warmed, conveniently by slipping it up the arm of the operator for a few seconds, then well oiled, and passed gently along the urethra into the bladder. (Fig. 430.) Its cavity is explored, first along the inferior surface by raising the handle of the sound and passing its convexity from the neck of the bladder in a sweep backwards; then, the bladder should be explored laterally, by revolving the handle from side to side between the fingers and thumb; lastly, the instrument should be withdrawn to the neck of the bladder, and the point turned downwards to the depressed space behind the prostate, and then upwards to behind the pubes. The space behind the prostate may sometimes be advantageously tilted forwards by introducing the finger into the rectum; a proceeding chiefly requisite in old persons.

In all these manœuvres, the instrument is used with a gently tapping motion, in order to strike the stone. Failing to discover a stone in the recumbent position, the bladder should be sounded with the patient standing up, and with a more or less than moderately distended state of the cavity. These resources having failed to present the stone, a second exploration may be made in the course of a few days.

The knowledge gained by sounding comprises more than the fact of the presence of a stone. Its *situation* is generally found to be on one side of the neck of the bladder, more frequently to the right; or when small sized, it usually lies backwards towards the fundus or buried in the space behind the prostate. (See Fig. 430.) Its *size* is less clearly ascertainable, but this may be guessed by observing the extent of hard surface over which the sound passes and the readiness with which the stone is found in all conditions of the bladder. By introducing a lithotrite, the dimensions of the calculus can be measured in all directions, as indicated by the separation of the blades. The *shape* of the *surface*,—whether rough or

smooth, is tolerably perceptible to the touch ; and the *density* or hardness of the stone can be estimated almost precisely by the sound elicited on percussion with the instrument—by, in fact, *sounding*. A hard calculus, as the oxalate of lime or uric acid calculus, rings when struck, so as to communicate a click audible to a bystander at perhaps a distance of some yards off ; a soft calculus, consisting of phosphates conveys a dull earthy sound, perhaps scarcely audible to the operator. The grating rough sensation and slight sound of a fasciculated bladder, perhaps overlaid with phosphatic deposit, must not be mistaken for a distinct calculus.

A second calculus, or the presence of several calculi, can sometimes be distinctly detected by the sound, a stone perhaps lying on each side of the bladder ; the introduction of a lithotrite will, however, surely determine the question, when one stone is seized and another struck with the instrument still holding the first in its grasp. Sir H. Thompson has devised and employed a modification of the lithotrite, which acts as a sound, catheter, and measurer. It goes by the name of Weiss's catheter-scoop with stop-cock.

Sounding is an operation not wholly free from danger. It may induce cystitis and peritonitis, terminating fatally. Sanson, Civiale, Crosse, and others have recorded such fatal cases. Hence, caution and gentleness should be observed in the practice of this familiar procedure. With all possible light-handedness in sounding, severe cystitis is sometimes provoked ; as happened in a case where Dr. Gross had sounded a young man, who was, however, the subject of stone of twenty years' duration, and accompanied with chronic cystitis.

All the symptoms of stone are more or less *pronounced* according to the size and shape of the calculus, as a foreign body in the bladder. A large-sized stone is usually attended with more marked symptoms ; and an irregular, rough stone is productive of the most severe symptoms. The kind of calculus has some influence, but chiefly as depending on the constitutional diathesis. Phosphatic calculi imply also a disorganized state of the bladder or chronic cystitis, and thence the accompanying local and constitutional disturbance of this state. On the other hand, sounding may *fail* to discover the presence of stone, and such instances have occurred in the hands of the most experienced Surgeons ; as Cheselden, Pelletan, and Dupuytren. In some cases, *large* calculi, of the size even of a hen's or duck's egg, nearly filling the bladder, have escaped the most careful and minute examination ; instances of which are related by Verzascha, Benevoli, Duretus, Riverius, Marcellus Donatus, Chesneau, Valentin, Riolanus, Morgagni, Covillard, Tolet, Morand, Deschamps, and Chopart, and by Gross as having occurred in the practice of Sir B. Brodie. *Several* calculi cannot always be detected : Collot extracted from the bladder twenty-two previously undiscovered calculi, which were hard and the size of a hazel-nut. Failure has occurred also after *repeated* exploration, as in the hands of Abernethy, who thus failed to discover a large, rough, oval calculus. In some such cases, the stone has remained undiscovered for years, until *after death*. An instance of this kind I remember to have heard from the late Mr. Thomas Morton (Surgeon to University College Hospital) as having happened in his own practice ; an instrument had been constantly passed also by many eminent Surgeons during a period of fifteen years, and yet no stone was found until after death. In other cases, and not unfrequently, a stone may be distinctly felt at one time, and not at another ; a remarkable instance of which fell to my own lot. I had

distinctly touched a small stone, lodged apparently in the cul-de-sac behind the prostate, and it was also felt by other Surgeons; yet, a few days afterwards, when about to operate, I could not detect the stone as the patient lay on the table, nor could it be discovered by Mr. Coulson Senr., or by Mr. Gutteridge; the latter skilled lithotomist having explored the bladder in various states of distension and the patient standing up. In about a month afterwards, the patient came to me with the stone in his hand; he told me that he had been seized with an intolerable desire to pass water, and as if the passage would burst, when the stone suddenly shot out and rolled across the room. Lastly, a calculus may be found *apparently*, by sounding; and then the unhappy mistake has been made, of cutting for stone and finding none. This misadventure has, however, happened to the most experienced Surgeons; to Cheselden, who on three occasions cut and found no stone, Crosse also, Roux, and Dupuytren, each of whom have thus performed abortive operations. Velpeau was acquainted with four such instances, and S. Cooper knew of seven.

*Encysted* calculus is so named when the stone is lodged in a cyst or pouch of the mucous membrane, between the muscular fasciculi of the bladder. The symptoms of stone—as caused by a loose, hard body rolling about in the bladder, are necessarily *absent*. There may be some pain and weight, with increased frequency of micturition, arising from the irritation of a foreign body; but there cannot be any aggravation of these symptoms after each act of micturition, and much increased by any jolting exercise—the stone being stationary; nor any sudden stoppage of the stream of urine, and constant liability to the admixture of blood. Then again, sounding gives less positive evidence as to the presence of a stone. The encysted condition may be suspected; if the stone be struck just once in a way,—when its exposed surface is hit by chance, and if it be always found at the same part of the bladder; or if the stone can sometimes be easily felt and at other times not felt at all,—owing to its escape occasionally into the bladder and back again into the cyst. A large encysted calculus having been struck, may perhaps be defined with the bulb of the instrument; not as an isolated stone, but through the mucous membrane as a projecting tumour. This comparative absence of symptoms occurs also when a calculus, at first loose in the bladder, *afterwards* becomes encysted.

*Diagnosis.*—The symptoms of stone, taken severally, may, when *present*, be due to other diseases of the bladder. A pedunculated growth in the bladder may, during micturition, flap over the urethral orifice and thus abruptly arrest the flow of urine. Ulceration of the prostate, or malignant disease of the bladder, both give rise to hæmorrhage. Lastly, the pain and vesical irritability may be sympathetic of an impacted and inflamed testicle within the inguinal canal, in the more rare case of undescended testis. We should therefore not be misled by the presence of any one symptom, but be guided by an *association* of the symptoms in respect to urinary calculus, as in the diagnosis of nearly all other diseases. Even the positive evidence afforded by sounding will often be masked when the prostate is enlarged. And, as Sir B. Brodie first observed, the last mentioned symptoms, pain and vesical irritability, are often much diminished by this prostatic condition; owing probably to the enlargement protecting the more sensitive neck of the bladder from the weight and friction of the stone. Difficulties, and sources of fallacy, in the way of sounding may be thus enumerated; a large and deformed bladder; a

contracted bladder, unable to contain fluid; a sacculated or encysted bladder; an irregular hour-glass contraction of the bladder, obstructing the passage of the sound into one of the compartments; calcareous matter adherent to the walls of the bladder; calculi in the prostate and urethra; enlarged and roughened prostate; and tumours at the neck of the bladder. The calculus itself may be coated with blood or mucus.

In the *female*, the symptoms of stone are similar to those in the male. Sounding is very easily accomplished, the straight and short urethra readily admitting the instrument and exploration of the bladder. The sound should, therefore, be shorter and less curved. By introducing the fingers into the vagina, the stone can be tilted forward, thus facilitating the examination.

*Consequences, and Terminations of Stone in the Bladder.*—The bladder, prostate, ureters and kidneys, undergo important structural changes, chiefly of a destructive character. With these changes in the urinary apparatus, exhaustive constitutional disturbance takes place. The bladder becoming extremely sensitive, especially behind the prostate where the calculus commonly rests, the urine is expelled at short intervals, and a contracted state of the bladder ensues. Sometimes, however, it falls into an atonic and dilated condition, with retention of urine, which undergoing decomposition assumes an ammoniacal and offensive character. In either state, more particularly the latter, chronic cystitis frequently supervenes, subject occasionally to attacks of acute cystitis; with muco-purulent urine. A fasciculated condition of the interior of the bladder usually results, in consequence of an hypertrophied development of the muscular bands beneath the mucous membrane; and not unfrequently between these fasciculi a hernial protrusion of the mucous membrane occurs, forming a pouch or cyst, in which the calculus is apt to lodge, as an encysted calculus. An ulcerative and discoloured sloughy state of the mucous membrane sometimes sets in; or a parietal abscess may form, which opening into the bladder, may receive the stone into its sac, and thus the calculus becomes encysted. Perforation of the bladder has been known to occur, allowing the stone to escape into the peritoneum, or perhaps into the rectum, vagina, or perineum. Pelvic cellulitis sometimes occurs, with diffuse suppuration. These more extreme results have probably been induced by injudicious sounding. The *prostate* usually becomes in some degree enlarged, whereby a depression or pouch forms behind it, as a frequent receptacle for the stone. The *ureters* undergo less marked changes; generally they are somewhat dilated, and thickened by chronic inflammation, especially at the pelvic portion adjoining the kidney. This organ is the seat of the most serious and ultimately fatal disorganization. Thus, the *kidneys* may be affected with chronic nephritis; and sometimes with the acute form of this disease, terminating in suppuration and a speedily fatal issue by uræmia or pyæmia. Degeneration more commonly takes place as the consequence of chronic nephritis, and thence death ensues from albuminuria.

This, the ordinary course of stone in the bladder extends over a longer or shorter period of years: varying very much according to the kind of calculus, the constitution, and age of the patient. Nevertheless, the course, although more or less slow and the symptoms more or less severe, is always progressive in its tendency to a fatal issue. As a set-off to this mode of termination, a spontaneous cure now and then takes place, by the expulsion of a small stone through the urethra in the act of straining micturi-

tion; and far more rarely, ejection of the stone has occurred by ulceration of the bladder through the rectum, vagina, or perineum.

*Treatment.*—The *remedial*, as well as the *preventive*, treatment of vesical calculous affections, comprises those general measures—medicinal and hygienic—which have reference to the calculous diathesis, in each particular kind of urinary deposit; and also, the various morbid conditions of the urinary organs, resulting from the presence of calculus as a foreign body; chiefly irritability of the bladder, cystitis and nephritis. The former, or specially constitutional treatment, is considered in the “Practical View of Urinary Pathology” to which I have already alluded; while, the inflammatory conditions of the bladder and kidneys are treated, the one under Diseases of the Bladder in this work, the other in works on the Practice of Medicine.

*Operations.*—The treatment of Stone in the Bladder consists of the various *operative* procedures appropriate for the removal of Stone. Three methods have been devised, two of which are established Operations; (1) lithotomy or the extraction of stone by a cutting operation; (2) the removal of stone mechanically by instruments, without a cutting operation—as by lithotrity or crushing in the bladder and extraction piecemeal through the urethra, or sometimes by simple dilatation of the urethra; (3) solution of Stone, by chemical agents or “lithontriptics,” or by the agency of electricity—“electrolysis.” Having regard to the desirability of these several methods of procedure, it might seem proper to notice the latter, or removal by solution, first; but in consideration of the far superior efficacy of the other two methods, they will be described almost exclusively; and first lithotomy, as being the operation perhaps most generally applicable.

LITHOTOMY, or the operation of cutting for Stone in the bladder, has been performed in various ways; both as with regard to the seat of operation and the method of its performance. There are three situations in which the bladder may be entered—in the perineum, the supra-pubic or hypogastric region, and through the rectum; thus indicating three principal operations of lithotomy—perineal lithotomy, the supra-pubic or high operation, and the recto-vesical operation. Perineal lithotomy comprises four varieties; (1) the ordinary *lateral* operation of Cheselden, and as modified in detail by Key, Liston, and other modern lithotomists; (2) the *median* or Marian operation, revived by Vacca, and as modified by Civiale, Buchanan, and established in modern surgery by Allarton; (3) the *bilateral* or transverse operation of Dupuytren; (4) the *quadri-lateral* section of the prostate by Vidal de Cassis.

No branch of Surgery possesses a history more interesting, curious, and romantic, than that of lithotomy, and its comparatively recent substitute—lithotrity; and nowhere is the temptation so alluring to an author in love with his Profession, to trace the gradual development of surgical principles and their application in practice. Nor would such an history be out of place in a work embracing the *Science* conjoined with the Practice of Surgery. But the necessary allotment of space forbids that which would be a somewhat lengthened diversion.

*Preparation of the Patient for Lithotomy.*—Some Surgeons, as Key, have paid great attention to the state of the patient's constitutional health preparatory to operation; other Surgeons of equal eminence, as Liston, have not deemed it necessary to delay the operation by much preparation. The nervous system being tranquil, or subdued by an occasional

opiate, the skin acting freely, and the urinary secretion having been corrected, as far as possible, by alkalis or acids, according to the character of the calculus; the bowels should be well relieved by mild purgatives, and the rectum especially must be emptied by an enema of castor oil and gruel on the morning of the operation. On no account should the operation be performed until the enema has come away, the loaded state of the bowel much increasing the liability of wounding this part.

*Instruments.*—Certain arrangements, which although simple, are indispensable to the safe performance of lithotomy. A firm, even, operating table, lightly covered with a doubled blanket so as not to present any thickness into which the buttocks might sink unevenly; a piece of waterproof covering being placed over the blanket, of sufficient length to hang down over the end of the table. Pillows are requisite to support the back. A firm stool is the most convenient seat, and it must be of such height relative to the table, that the patient's buttocks shall be level with the operator's breast when he sits down. This adjustment is easily made by experience. A small low table or a large chair should be provided, on which the instruments are laid out; and placed to the right of the operator, so that he can readily help himself during the operation, independently of any assistant for this purpose. The appliances and instruments requisite are;—a pair of bandages of coarse flannel, each about three yards long and two inches in width; two lithotomy knives or scalpels; namely, a sharp-pointed, straight-backed knife, and a blunt button-pointed knife, somewhat curved backwards towards the end; a staff, boldly curved and deeply grooved on its left side with a good pit at the end of the groove, the size of the instrument being sufficient to fill the urethra, and the handle roughened; lithotomy forceps, straight and curved; scoops of different sizes; a bladder-searcher; and an injecting syringe, capable of holding about a pint, the nozzle fitting to a catheter. To these may be added, a gum-elastic urine-draining tube with rings at its outer end, whereby it can be fixed in the bladder with perineal tapes, after the operation. This instrument was invariably used by Liston, and subsequently by Sir W. Ferguson in the earlier portion of his career; it has also been employed by other excellent lithotomists, and as a Listonian pupil, I naturally followed for a time the example of the great master. But the tube was, I believe, never used by Coulson, nor by other men of large experience, and it has now fallen into general disuse.

*Lateral Operation.*—Four assistants at least are required for the performance of this operation; one to administer chloroform, one on each side of the patient to fix the perineum in the proper position as presently described, and a fourth to take charge of the staff. A fifth assistant might be convenient to hand instruments, unless they are placed within easy reach of the operator, when sitting down.

The operation consists in cutting on a staff into the bladder,—by a preliminary superficial, perineal incision to reach the instrument, followed by a deep or prostatic incision in the groove of the staff to enter the bladder; and the extraction of the stone. Thence the instruments essentially requisite, are simply three; a staff, a knife, and forceps. (Fig. 431.)

The patient is placed recumbent on the table, and chloroform administered. Then the bladder having been previously emptied of urine, should be injected with tepid water to the amount of about six ounces, in order to steady the bladder and expose the stone to the grasp of the

forceps. Sounding should now be performed, immediately before the operation is commenced,—when the patient's bladder is in position. This may be done with an ordinary sound; but it is preferable to at once in-

FIG. 431.

roduce the staff (Fig. 432) of sufficient size to occupy the urethra—and, using it as a sound, the stone must be distinctly felt and its situation ascertained. This is an imperative rule in regard to lithotomy. If the

FIG. 432.

stone cannot be felt at the time of operating, the operation should be unhesitatingly postponed; if it can be felt, the operation is proceeded with. The patient is brought to the end of the table, so that his buttocks

FIG. 433.

resting on the edge shall project a little beyond it; the legs are to be drawn up and the hands and ankles firmly bound together with the lithotomy bands (Fig. 433), as thus,—either hand being placed on the outer side of the ankle and made to grasp the foot, both are securely joined in this position by a figure-of-8 application of the band. Or the couplet leathern straps used by Sir W. Ferguson is a more simple, and equally secure con-

FIG. 434.

trivance. (Fig. 434.) Then, the side-assistants, taking each a foot

in his hand on the inner aspect of the foot, and placing the patient's knee in his axilla, the limbs are drawn sufficiently apart to fully expose and throw out the perineum; at the same time observing that it inclines to neither one side nor the other, but is fixed perpendicularly, or horizontally to the table, and maintained in this position throughout the operation. Unless these two assistants attend only to this, their simply mechanical but important duty, that of exposing and balancing the perineum, instead of attempting to hang over and see the operation; they will assuredly disturb the visual line of the operator and thus embarrass him in his incisions and manipulations.

The staff is now given in charge of an assistant, standing on the patient's left, with the injunction to hold it firmly, in the perpendicular direction, and hooked up against the symphysis pubis. (Fig 435.) I

FIG. 435.

once heard Mr. Coulson request a young assistant to hook up the staff as if to the ceiling; and I thought that illustration as to the mode of holding the staff, very suggestive of the right way. Some Surgeons prefer that the convexity of the staff should be made to bulge slightly forward in the perineum; others that it should be turned somewhat towards the left of the perineum; while some prefer that it should be depressed and held in contact with the stone. The assistant holds the staff between the thumb and fingers of his right hand; the left hand is used to raise the scrotum from the raphé running down to the rectum. Thus then, the space between the urethra and the rectum is exposed as much as possible, so that the one can be more readily approached without the risk of wounding the other.

The Surgeon seating himself on the stool in front of the perineum, thus exposed; he shaves the integument on the left side, and introduces his finger into the rectum to know for certain that the bowel is empty and to induce its contraction; whereby any remaining feculent matter will be expelled, and the contracted state of the bowel diminishes the risk of its being wounded during the deeper incision. Then, with his left hand thumbing the tuberosity of the ischium and the ramus on the left side, he feels also, with the point of the fore-finger, the sort of depression below the bulb of the urethra, in the middle line or raphé, which lies over the curve of the staff; a point about one inch and a half in front of the anus, and corresponding to a part of the instrument which

in a thin perineum can often be plainly felt. The land-marks of his incision having thus been clearly defined; the Surgeon rests his left hand on the right half of the perineum and indicating with the fore-finger the above spot, he plants the lithotomy-knife in the raphé or just to the left of it, and carrying the blade in a straight line obliquely downwards and outwards between the anus and tuberosity of the ischium, but nearer to the latter, terminates the incision at a point just below the anus. A *free* but superficial *perineal* incision is thus made. (See Fig. 435.) The skin, superficial fascia and fat are divided; but the depth of the incision, varying according to the perineal obesity, is above rather less than an inch, while below, the knife sinks a little more deeply into the ischio-rectal fossa. The upper half of this incision—above the anus, leads to the staff; the lower half,—by the side of the anus and below it, facilitates the extraction of the stone. The point of the fore-finger of the left hand is now drawn firmly along the bottom of the wound, between the left erector penis and accelerator urinæ muscle overlaying the bulb of the urethra, so as to separate these parts; then, using the finger to protect the rectum, by pressing it somewhat downwards and to the right, any further resisting structures are divided by a slight touch or two with the knife. Thus are divided, the transversalis perinæi muscle and artery, and the base of the deep perineal fascia or triangular ligament of the urethra, which latter sometimes in elderly persons presents a tolerably firm bar to the finger. The finger is then directed upwards from the rectum, as a guide to the staff; the groove of the staff is felt just in front of the prostate, in the membranous portion of the urethra and as covered therefore with this membranous structure stretching across the groove. By a little compression at this spot, the nail of the finger is lodged fairly in the groove; and then the point of the knife, with the cutting-edge downwards, is slid along the finger *over* the nail, and penetrating the membranous urethra, is at once inserted into the groove of the staff. This relative position of the finger to the knife will securely protect the rectum, —itself also pressed downwards and to the right; and which, from its

FIG. 436.

proximity beneath the prostate, is especially liable to be wounded at this part of the operation,—the commencement of the *deep* or *prostatic* inci-

sion. (Fig. 436.) The knife is now pushed firmly along the groove of the staff, through the prostatic portion of the urethra and the prostate, with a slight inclination of the blade downwards and outwards; thus incising or notching the prostate *laterally*, in the same direction as the external or superficial incision; while the point of the blade by slightly depressing the handle to a very limited angle with the staff, follows the curve of the staff, until the bladder is entered. If the knife directed sideways, runs firmly in the groove of the staff, so as not to slip out to the left, the blade cannot go wrong and the incision must be right. The bladder is known to be entered by resistance ceasing, and perhaps a gush of water taking place. This incision may be made rapidly and boldly by a practised lithotomist; I have seen Liston run the knife along the groove right into its terminal pit, which the point of the blade might be heard to strike, even turning the point of the instrument. A less practised lithotomist must make the incision more slowly and cautiously. A *button-pointed* lithotomy-knife (Fig. 437) may be used more safely, as it

FIG. 437.

locks into and has a more secure hold in the groove of the staff. Such a knife was always employed by Coulson. In withdrawing the knife, it should pass over the finger, in the same direction as in introducing it, and still in the groove of the staff, so as not to enlarge the incision.

This—the deep or prostatic incision, is therefore essentially *limited* in its *extent* through the *prostate*; not exceeding twice the width of the blade of the knife, and certainly not passing beyond the base of the gland, where its *capsule* prevents infiltration of urine into the cellular texture of the pelvic cavity behind the prostate. This precaution is especially characteristic of the Listonian operation. On withdrawing the knife, the left fore-finger is pushed in after it through the prostatic incision into the bladder; and, if this manœuvre be executed adroitly, the introduction of the one follows the exit of the other,—the finger replacing the knife *before* the water escapes in any gush from the bladder. The finger, fitting into the incision, is made to enlarge the wound by a sort of twisting, or tunnelling motion; whereby the opening is dilated and the prostate somewhat split, as with a blunt gorget instead of having been cut freely by

FIG. 438.

the knife. As the finger proceeds, at the same time—the stone is felt for. This double duty of the finger, as a dilator and a searcher, may be conveniently performed, while the Surgeon is taking the forceps with his

other hand from an assistant, or from a basin of warm water at his side. Having thus entered the bladder, and found the stone; the assistant is directed to withdraw the staff. Then the Surgeon introducing the closed blades of the forceps over the finger, he slides them into the bladder; when, on somewhat dipping the forceps and opening the blades (Fig. 438), usually with a sort of sweep from left to right across the fundus of the bladder, the stone is at once caught and seized, whereby the instrument feels suddenly locked. The size of the stone may be estimated by observing how far the handles are separated. If it seem to be seized in its long diameter and too large for extraction; the stone may be shifted by a jerk of the forceps, or disengaged and re-seized, so as to be extracted without lacerating or bruising the neck of the bladder.

*Extraction* should be performed slowly, and by working the instrument gently backwards and forwards to gradually dilate the prostatic aperture; bearing downwards also in the direction of the axis of the pelvis, in order that the widest part of the arch of the pubes may be available for the extraction, and the lower part of the perineal incision which facilitates this concluding part of the operation. The forceps lie in the axis of the pelvis, and are withdrawn, in the same direction as obstetric forceps. After removing the stone, the finger should be re-introduced into the bladder to search for any other stone which may be present; or the *searcher* can be used for this purpose to reach parts of the bladder not readily accessible to the finger, as in front above the pubes. And, as *in* the act of withdrawing the knife through the prostatic incision, the finger at once followed it; so also *in* withdrawing the forceps, the finger is again made to follow this instrument; that thus the entrance to the bladder

FIG. 439.

shall never be lost—an injunction the more imperative when the staff, as a guide, has been withdrawn. No second stone having been discovered, the operation is completed.

*Fracture* of the stone sometimes occurs, in seizing or in extracting it; and generally as the result of undue force in using the forceps, aided perhaps by the brittle character of the stone, as when the calculus is phosphatic. This accident should be carefully avoided; for the fragments are apt to injure the bladder in any attempt to extract them, and it necessitates the repeated introduction of an instrument. The fragments are best removed by means of the *scoop* (Fig. 439), with the fore-finger resting on the end of this instrument and keeping the stone from slipping out of the bowl. The bladder should then be thoroughly washed out with tepid water, injected by a strong brass syringe through a tube introduced by the wound. Several small calculi are most readily removed in like manner—by the scoop.

FIG. 440.

A gum-elastic tube (Fig. 440) may then be introduced through the wound into the bladder, and retained in position by perineal tapes. This instrument was formerly deemed serviceable for two purposes; as a means

of somewhat arresting any oozing hæmorrhage; and for keeping the wound free of coagula, thus affording a clear passage and preventing the infiltration of urine. But the latter risk is avoided by the limited prostatic incision; and the former advantage is more than counter-balanced, in most cases, by the incessant concentration of the patient's attention to his bladder.

I have thus described the lateral operation of lithotomy as consisting of three steps—two of which are incisions—a superficial or perineal, including a deeper touch or two with the knife, and the deep or prostatic incision; and then, extraction of the stone from the bladder. It should, however, be observed by the Student, that although these steps are described separately, they are performed successively as one continuous operation. The procedure consists in an *alternate* application of the left fore-finger and the knife, or the forceps. Commencing with the indication of the point for entering the knife in the perineum, this is followed by the superficial perineal incision; then, the finger is used successively, as a protector, guide, blunt-gorget, and searcher; with the knife alternately, in the perineal wound, the groove of the staff in the membranous urethra, the prostatic urethra, and bladder; followed by the forceps, also used alternately with the finger, in the bladder. The textures are successively divided downwards and outwards, away from the rectum, by *lateralized* incisions; and they together form an oblique *conoidal* wound, having its base externally in the perineum, and the apex in the prostate.

*Position of the Hand and Knife.*—Much difference of opinion has been held in surgical works of authority, and different delineations have been given, as to the manner of holding the knife in lateral lithotomy. I specially allude to this question on that account alone, and not because of its intrinsic importance. So long as the proper incisions are observed, both with regard to their situation, direction, and extent, it can be of little consequence how the knife is held in executing them. The Surgeon will best accomplish the object he has in view, in the manner most convenient to the movement of his own hand; a matter of personal experience which must necessarily vary with the shape and mobility of this member in different operators. In making the superficial or perineal incision, the knife is generally held *under* the hand; and in making the deep or prostatic incision, this position is still maintained by Sir W. Fergusson (see Fig. 436), and most other lithotomists. Liston, however, would appear to have held the knife *above* the hand, in making the latter incision, as here depicted. (Fig. 441.) This wood-cut is the identical one which originally appeared in Liston's Practical Surgery, and for the use of which (and many other wood-cuts) in this work, I am indebted to my Publishers. It is described as being a representation of "the position of the hands and knife," at the commencement of the second incision, as shown "in a very correct sketch of the viscera of the pelvis, with their relative size and position; and which has been copied more than once without acknowledgment." (Fourth Edition, 1846, p. 509.) But, notwithstanding this record by Mr. Liston, on the point in question; as an old Hospital pupil, having enjoyed unusual and prolonged opportunities of witnessing the operations of the great lithotomist, I can corroborate the statements of Sir W. Fergusson, Mr. Erichsen, and Mr. Cadge of Norwich, that Mr. Liston held the knife *under*-hand; and I particularly well remember also that, in entering the point of the knife into the groove of the staff, his fingers were enclosed around the blade, apparently to

cover the edge, and fit the point into the groove securely—the instrument being then sent forward from the palm of the hand.

*Cutting on a Straight Staff.*—This mode of performing the lateral operation was originated by Aston Key, at Guy's Hospital, where it is still practised, and by other Surgeons. The straight staff is more liable to be tilted out of the bladder than the curved one; and therefore, the

FIG. 441.

end of the staff should always rest upon the stone in performing the operation with this instrument.

Having reached the staff by the perineal incision, which has to be carried deeper than to reach the curve of the ordinary staff, the point of the knife is entered into the groove; then the Surgeon, withdrawing the left fore-finger from the wound, takes the staff from the assistant previously in charge, and depressing the handle brings it down parallel with the axis of the pelvis, so as to present a direct passage to the bladder. In doing either of these acts, special care must be taken lest the knife slip out of the groove. Feeling certain that it still remains in; the Surgeon lateralizes both staff and knife, in contact, to the left of the perineum, corresponding to the external incision, and pushes the knife onwards along the groove into the bladder; withdrawing it in the same direction, so as to incise the prostate only to a limited extent. Here again, in this nearly parallel mode of using the staff and knife, special caution must be taken lest the point be tilted out of the groove by the front of the prostate; when, instead of entering the bladder, it would pass down into the pelvic cavity. This may be obviated by depressing the handle of the knife to a *limited* angle with the staff, so as not to incise the prostate too far back. Then, having entered the bladder and withdrawn the knife, this instrument is laid aside; the staff is now transferred to the right hand, and the left fore-finger, introduced into the wound, is guided by the staff into the bladder and to the stone. The finger resting on the stone, the staff may

be withdrawn; the forceps is introduced along the finger, and the operation completed.

*Parts cut, and Parts to be avoided, in Lateral Lithotomy.*—If the operation be conducted on the principles laid down, the question of the “parts” concerned, is more an anatomical investigation than a surgical consideration—more a Student’s question, than of practical consequence. The parts necessarily *divided*, in their order from without inwards, are;—the skin, superficial fascia and fat, with the inferior hæmorrhoidal vessels and nerves passing across the ischio-rectal fossa; the transverse perineal muscle and artery, with probably the superficial perineal artery and nerves; the base of the triangular ligament and the deep transverse urethral muscle; the membranous urethra and constrictor muscle; the prostatic urethra, and the prostate to a limited extent in its left lateral lobe, including the “ligamentous ring or band” around the neck of the bladder, but not the capsular boundary formed by the reflexion of the recto-vesical portion of the pelvic fascia; external to the capsule, some of the anterior fibres of the levator ani muscle will be divided, and within the capsule, a plexus of rather large-sized veins must be severed—in the prostatic incision.

The annexed figure (Fig. 442) represents the “parts cut in Lithotomy,” as depicted in Liston’s Practical Surgery.

In addition to the vessels necessarily divided, certain vascular *deviations* occasionally from the normal arrangement render other vessels liable to be wounded. Thus, the artery of the bulb, when it arises from the pudic near the tuber ischii, crosses the line of incision. The accessory pudic, as an occasional substitute for the pudic when defective, lies on the posterior edge of the prostate, and would be divided by the prostatic incision, if this were extended backwards to the base of the gland. Arterial branches, or the venous plexus, on the surface of the prostate, are each

FIG. 442.\*

sometimes unduly enlarged, and become a source of hæmorrhage, arterial or venous.

\* 1 and 2, fibrous band around the orifice of the bladder; 3, opening of ureter; 4, descending muscular fibres, with transverse fibres towards the cavity. (John Marshall.)

The parts to be *avoided* in the operation, are in anatomical works enumerated;—as the rectum, the pudic artery, where it courses forwards under cover of the ramus of the pubes; the bulb of the urethra; and the artery of the bulb, which normally passes inwards transversely about half an inch above the base of the triangular ligament, between it and the other or deep layer of the perineal fascia. Of these parts, the rectum will be avoided, by having the staff well hooked up, protecting the bowel with the finger and lateralizing the knife parallel with the bowel—particularly in an old person whose rectum is commonly dilated into a pouch just above the anus, sometimes even wrapping around the prostate from side to side. The precaution of emptying the bowel should also be observed. The other parts mentioned are less readily wounded, or are less important. The pudic artery will be avoided by not turning the knife too much outwards in making the deep incision. Posteriorly this artery is securely lodged under cover of the tuber ischi. The artery of the bulb, sometimes a serious source of hæmorrhage, may be avoided by not cutting too freely upwards towards the groove of the staff; but an irregular course of the vessel cannot be foreseen or avoided by any plan of incision. Lastly, the bulb of the urethra, a source of venous hæmorrhage, may be avoided by directing the point of the knife obliquely upwards beneath its projection, in the act of penetrating the membranous urethra. But, I concur with Mr. Skey, in not attaching much importance to a wound of the bulb; and I have no doubt it not unfrequently occurs without any evil consequence.

As compared with these anatomical niceties, it will be found that while anatomy plans the landmarks and limits of the incisions—perineal and prostatic; the *pathological* conditions of the prostate and of the bladder are of more surgical importance in completing the operation.

*The Lateral Operation in Children.*—Lateral lithotomy is performed in the same way in Children as in Adults; but the anatomical condition of the parts under the age of puberty and especially in childhood, affects the performance of this operation. The anatomical peculiarities alluded to are chiefly four;—looseness of the perineal cellular texture in the recto-vesical space; the small size, thinness and weakness of the membranous urethra; the rudimentary small size of the prostate; and the position of the bladder—it being situated more in the abdomen than in the pelvis. These conditions severally affect the operation in its first part—that of entering the bladder; extraction of the stone is not attended with any special difficulty.

Thus, the superficial perineal incision having been made correctly, the *loose cellular texture* easily yields and gives way under the finger, forming a distinct, smooth-walled cavity or false-bladder, in the recto-vesical space; which resembles the interior of the bladder. A very little groping with the finger, in the wrong direction—*downwards* will form this deceptive cavity; into which the finger readily enters as if into the bladder. Perhaps also the membranous urethra has been penetrated, whereby the urine dribbles away and the bladder gradually collapses; both circumstances apparently confirming the belief that the finger is really in that cavity. Indeed the latter condition affords more room for the easy enlargement of the false bladder. In this anxious and perilous moment, two points of distinction should be remembered; this false bladder presents *no neck* through which the finger should pass to gain admission, nor can the *bare* grooved staff be felt along the back of the finger when in-

roduced into the cavity. Besides both these negative features of distinction; *above* this cavity, near the symphysis pubis, lies the staff leading to the bladder; and which can be plainly felt on directing the finger from the scene of mischief, obliquely upwards to that spot. Hence, the practical inferences are these; in approaching the staff, to avoid making anatomy by a too free use of the finger as a guide; and to direct both it and the knife upwards to the more highly situated staff, instead of heedlessly slipping into and working in the interval between the bladder and rectum. A precaution before operating should also be observed; that of sufficiently distending the bladder with water, to lower its position in the pelvis and to steady its neck. The same kind of misadventure may occur between the neck of the bladder and the pubes, by misuse and misdirection of the finger *upwards*. It need scarcely be added, that in either such case, the little patient remains unrelieved, and dies with the stone in the bladder. Yet this calamity has happened to some of the most skilful and experienced lithotomists—past and present.

Again, in endeavouring to hit the membranous urethra and lodge the point of the knife in the groove of the staff; the urethra being of *small size*, it may be so cut about as to be nearly severed from the prostate. Or, if the point of the finger be not insinuated well into the opening, or if any undue force be used in passing it into the bladder; the *thin* membranous urethra may be torn across, and the neck of the bladder driven backwards on, or off, the staff,—an accident more likely to happen when the urethra has been nearly severed.

Thus then, in opening the urethra, as in approaching it, *fiddling* with the knife must be avoided; and in both procedures, any *forcible* use of the finger will also be mischievous.

The *rudimentary size* of the prostate, and the *high position* of the bladder, will both necessitate a more upward direction of the point of the knife, in making the prostatic incision. And it should be remembered that this incision must necessarily almost always, if not invariably, extend through the whole of the small prostate, in its left lobe; yet without any evil consequence.

In entering the neck of the bladder, the feeling is that of passing through a small ring; without riding over the sort of chestnut-like projection upwards of the prostate, and which may be like a half-orange in an elderly man.

When the prostate has been detached from the membranous urethra and the neck of the bladder recedes before the point of the finger; all the presence of mind and dexterity of the Surgeon will be required at this trying moment of peril and anxiety. Much will depend on whether the staff still remain in the bladder, as a guide. If so, the fore-finger should be passed most cautiously and gently along the groove, and a slight hooking-movement made at the neck, so as to draw down this part. It may then be notched, by insinuating the knife along the finger, which can thus be fairly entered. If the staff be out of the bladder, or has been withdrawn; the position of both patient and Surgeon is most critical. It may be possible to re-introduce the instrument, and then proceed as just directed. Failing to accomplish the first step, the attempt to hook down the neck of the bladder should never be resorted to,—in the absence of a *guide*. The finger or any searching instrument will only pass deeper and deeper with increasing damage, and inevitable death result. Moral courage is here the better part of valour, and any further operative interference

should be resolutely abandoned. The urethra may heal, restoring the continuity of the canal, when the operation can be repeated and brought to a happy issue.

**DIFFICULTIES, AND ACCIDENTS, DURING LITHOTOMY.**—The *Difficulties* which may occur in the performance of the lateral operation relate either; (1), to entering the bladder; or (2), to seizing and extracting the stone. The first occur more especially in operating on children, and have been already described; the second kind of difficulties happen more commonly in adults. Thus, in *children* two difficulties are very liable to happen, in endeavouring to enter the bladder; the formation of a false bladder in the recto-vesical space, and the incised or torn detachment of the neck of the bladder from the membranous urethra. In *adults*, the first of these difficulties has occurred as the result of prolonged *boring* with the finger in the cellular interval between the bladder and rectum.

(1) A *deep perineum* presents obstacles to *entering* the bladder. The depth of perineum may be due to fat, in a corpulent person; or to an enlarged prostate, in an elderly person. Both conditions not unfrequently co-exist, coupled also with an indurated state of the prostate. A forefinger of average length can perhaps scarcely reach the bladder, if at all; and the prostatic condition of enlargement and rigidity obstructs the introduction of the finger. The blunt-gerget, formerly in ordinary use, is here very appropriate; as affording the means of dilating the incomplete incision in the enlarged and indurated gland, and of gaining access to the bladder beyond reach of the finger.

(2) *Seizure and extraction* of the stone may present difficulties dependent on several conditions;—depth of the perineum, particularly when due to an Enlarged Prostate; an Encysted, or an adherent state of the stone; the Position, Size and Shape of the stone; Rickety deformity of the pelvis, in its antero-posterior diameter, or by narrowing of the pubic arch. These various conditions interfere with the use of the forceps; either in introducing the instrument into the bladder, in seizing, or in extracting the stone.

*Enlargement of the Prostate*, which places the bladder beyond reach of the finger, renders the introduction of the forceps difficult; and seizure of the stone more so, owing to the liability of its falling into the depression behind the prostate, and thus escaping the sweep of the forceps. In extracting the stone through an enlarged prostate, difficulty may be experienced; and rather than bruise or lacerate the parts, it would be proper to incise the opposite side of the prostate towards the right tuberosity of the ischium; thus forming a bilateral section of this body, without making any additional perineal incision.

*Encysted calculus* is not of very common occurrence; but if this condition be found in exploring the bladder with the finger, the course to be taken by the Surgeon should depend entirely on the size of the aperture of the sacculus. A small aperture will preclude the possibility of removing the stone, without endangering life. A large opening, or a partially encysted condition, may allow the stone to be liberated. This can sometimes be effected by a fortunate catch with the forceps; in one case, by Collot, changing the position of the patient proved successful in dislodging the stone; in another, by Sir B. Brodie, the orifice was enlarged with a probe-pointed bistoury, and the calculus turned out with the finger or scoop. The latter procedure is, obviously, extremely hazardous, since the bladder might easily be cut through into the peritoneal cavity. When, therefore,

the calculus cannot be otherwise removed, and with tolerable facility, the operation should, as Coulson observes, be abandoned. An encapsuled calculus was once found by Mr. Erichsen, in a child; the stone, about the size of a pea, being felt at the inferior fundus of the bladder, covered in by a kind of false membrane. This membrane was scraped through with the nail, and the stone removed with a scoop. The cyst attached, was about the thickness of ordinary writing paper, of a reddish colour, consisting of organized fibro-cellular tissue, and resembled mucous membrane. Excepting a slight attack of secondary hæmorrhage on the eighth day after operation, the patient made a good recovery.

*Enveloping folds* of mucous membrane are sometimes met with, the stone thus eluding the grasp of the forceps. This mechanical difficulty must be overcome by manœuvre with the forceps, or by the more direct and safe means of the finger and scoop.

*Hour-glass contraction* of the bladder, the stone being placed in the upper compartment, will probably necessitate recourse to the high or supra-pubic operation of lithotomy.

An *adherent* state of the calculus has been doubted by some authors; but an indisputable case is recorded by Mr. Shaw in the Transactions of the Pathological Society, vol. vi. The adhesion of the mucous membrane to the stone was effected by fibrous tissue, the fibres dipping into the calcareous substance; and this union was so firm that it resisted separation by tearing with the forceps. In extracting phosphatic calculi, the deposit of rough calcareous matter on the rugæ of the bladder must not be mistaken for a distinct calculus; any attempt to remove the former would of course prove disastrous by tearing away the mucous membrane with the deposit.

*Position of the stone.*—Two parts of the bladder, in either of which the calculus may be situated, offer considerable difficulty to *seizure* of the stone. When lodged in a depression behind an enlarged prostate; the stone must be brought up by tilting the bladder with the finger introduced into the rectum, and then using a curved pair of forceps or a curved scoop. When situated above the pubes anteriorly, towards the upper fundus of the bladder; the stone must be lowered by compressing the abdomen, as Aston Key recommended, and then seizing with a curved forceps or the curved scoop. In one such case, Sir B. Brodie found the stone both encysted and adherent. Raising the pelvis will sometimes enable the forceps to grasp the stone, a resource which proved successful in a case on which Mr. Coulson operated.

*Shape and Size of the Stone.*—The shape of the stone may offer some difficulty to its *seizure* with the forceps. A round irregular stone, as a mulberry calculus, is grasped less readily than a flattened, smooth stone, which lies easily within the blades of the forceps. Irregular shaped, phosphatic calculi, present the greatest difficulty.

Both the shape and large size of the stone may offer considerable obstacles to its *extraction*. Three resources are practicable;—(1) section of the right lobe of the prostate, forming the bilateral section of this body, (2) crushing, splitting, or drilling up and breaking up the stone in the bladder—by means of strong lithotomy forceps, cutting forceps, or lithotrites,—thus performing perineal lithotrity; (3) the recto-vesical, or the supra-pubic operation of lithotomy. Of these procedures, section of the prostate is most practicable and the safest. It was recommended by Liston and Martineau, rather than use undue force in attempting to gradually

dilate the ordinary prostatic incision, which would cause bruising or laceration. The forceps still grasping the stone is held fast by an assistant, and the right lobe of the prostate is then incised towards the right tuber ischii, by passing the knife or a blunt-pointed bistoury along the blade of the instrument as a director. In this way, Martineau often enlarged the opening, repeating the incision two or three times. Crushing the stone in the bladder through the perineal wound, is a more dangerous procedure; the instrument required must be of some size and strong; its application may be attended with some injury to the bladder, which is often firmly contracted on the stone; and the fragments of stone, as sources of irritation or centres of secondary calculi, must be thoroughly removed by repeatedly injecting and washing out the bladder with tepid water. The recto-vesical, or the supra-pubic operation would be preferable to crushing, in most cases.

*Fracture* of the stone is apt to happen when the calculus is brittle, or soft; breaking into several sharp fragments, or squashing into a soft mortar-like mass. It occurs mostly to phosphatic calculi. This breaking-down of the stone results usually from too firm a grasp with the forceps; either lest the stone should slip away, or by pulling too high up and coming in contact with the pubic arch, or in consequence of the pressure requisite in extracting a large-sized stone. The fracture generally leaves a central stone in the blades of the forceps, which should be extracted; and the detached fragments removed by the repeated introduction of this instrument or the scoop, and the bladder thoroughly washed out. Detritus will probably still remain, and small fragments may be discharged through the wound for some days; then the bladder should be injected daily through a catheter passed down the urethra, and the water made to escape freely by the wound; the stream carrying with it particles of calculus. This plan should be continued until no more detritus is brought away. If the wound has healed, the fragments remaining must be washed out through the urethra, by means of a catheter, as after lithotrity.

*Rickety deformity* of the pelvis, although not a common cause of difficulty in lithotomy, may present insuperable obstacles in extracting the stone. If the brim of the pelvis be narrowed in its antero-posterior diameter; the difficulty of extraction will be increased in children, owing to the high position of the bladder. Narrowing of the pubic arch, which is always narrow in children, may quite preclude extraction, or even the introduction of the forceps. These conditions should be ascertained *before* operation, and supra-pubic lithotomy performed.

The *Accidents* which may happen during the lateral operation are:— (1) wound of the rectum; (2) hæmorrhage, arising either from the vessels necessarily divided, or from the pudic artery or the artery of the bulb, or from certain accidental deviations of these vessels, and from the prostatic or other veins; (3) wound of the bulb; (4) missing the urethra and entering the bladder beyond the prostate; (5) penetration of the posterior part of the bladder from within its cavity.

The three first named accidents have already been adverted to in considering the parts to be avoided in performing the lateral operation; and when either of these accidents occurs, the treatment should be conducted on ordinary principles.

(1) *Wound of the rectum* is important according to its size or situation. A small puncture, low down near the anus, may be left to itself; a little feculent fluid may escape from the perineal wound for some days,

along with the urine; but as granulation closes up, this ceases, and the urine is transmitted through the urethra. A larger-sized aperture, or when situated higher up the bowel, had better be dealt with at once and in the same way as fistula in ano. The bowel should be laid open into the perineal wound, by an incision from the accidental aperture downwards through the sphincter ani, so as to form one cavity. Granulation from the bottom may then restore the continuity of the bowel. Otherwise, a recto-vesical fistulous communication will remain.

(2) *Hæmorrhage* must be managed on ordinary principles; by ligature or torsion of any distinctly bleeding artery that may be accessible; or by pressure. The artery of the bulb is the principal source of serious, or even fatal hæmorrhage; and so also would be the internal pudic, as it can scarcely retract within the obturator fascia overlaying it; but this vessel is well protected under cover of the ramus of the ischium. Either vessel is best secured by compression; ligature being inapplicable in most cases, as the vessels cannot thus be reached. Compression is applied most effectually by means of digital pressure; provided the bleeding vessel can be commanded with the finger, and relays of assistants are at hand. In the course of fourteen or twenty-four hours,—according to cases related by South and Brodie, continued digital pressure succeeded in permanently stopping hæmorrhage from these vessels. The ramus of the bone offers an excellent counter-resistance to the finger. *Oozing* hæmorrhage, of a persistent character, may be effectually arrested by plugging the perineal wound. This is precisely the condition in which Liston's gum-elastic tube may be used with advantage, while free vent also will thus be given to the urine. The track of the wound is plugged with dossils of lint around the tube; or more conveniently, by pieces of sponge introduced into a conical bag of oiled silk attached to the tube, as devised by Mr. Hilton. The tube is kept free of coagula by the occasional introduction of an oiled feather. *Venous* hæmorrhage, proceeding chiefly from the prostatic plexus of veins, may be arrested in like manner. Hilton's contrivance has here proved very successful. A case is related in the Medical Times, 1855. Sir B. Brodie lost a patient within a few hours after operation, from venous hæmorrhage; every effort having been made in vain to arrest it. *Retrocedent* hæmorrhage, the blood, arterial or venous, passing back into the bladder, sometimes occurs and to an alarming extent. Bloody urine escapes by the wound, but the bladder becomes distended; there is dulness on percussion above the pubes, and faintness ensues. Injections of cold water should be used to wash out the bladder; and ligature or plugging applied, according to the nature and source of the hæmorrhage.

(3) *Wound of the bulb* is an accident of no serious consequence.

(4) *Missing the urethra, and entering the bladder beyond the prostate*, allows of infiltration of urine into the pelvic cellular tissue. Diffuse inflammation and death will almost necessarily follow. Yet this fatal accident has occurred, once in a way, to the most skilled lithotomists.

(5) *Penetration of the posterior part of the bladder*, is liable to occur from passing the knife too deeply along the groove of the staff; the point may slip out and penetrate the posterior wall of the bladder. An insufficiently injected bladder would be more exposed to this accident. I have never yet known it to occur.

In *children*, the accidents specially incident to lateral lithotomy, have been fully considered in describing the operation as performed before puberty or at an earlier period of life.

**AFTER-TREATMENT.**—When no accident has occurred during the operation, the treatment after lateral lithotomy is simple. The patient is placed on his back in bed, with his legs apart and the knees somewhat raised on pillows. The urine will thus drain away through the wound, as it is secreted; preventing the chance of urinary infiltration. A draw-sheet covered with Mackintosh cloth, having been previously placed under the buttocks, will enable the nurse to keep the patient clean and dry without altering his position. No dressing is required, a sponge or small spittoon-pot is placed under the wound against the nates to catch the urine as it drops. If Liston's gum-elastic tube has been passed up the wound into the bladder, and there retained by perineal tapes; this channel can be kept free from coagula and open for the distillation of the urine, by occasionally introducing an oiled feather. When I was a student, this precaution was observed so diligently, that the dresser in attendance sat by the patient's bed-side, the night after operation, for the purpose of thus freeing the tube. It was retained for about twenty-four hours, in a child; and about forty-eight hours, in an adult. By that time its retention was thought unnecessary; the sides of the wound having become glazed over with lymph, whereby the risk of infiltration will have ceased. An opiate should be given, and repeated when necessary, to secure sleep or at least quiescence; and diluent drinks allowed plentifully, with light fluid food, as milk, arrow-root or beef-tea, during the first three or four days. In an elderly person, it may be requisite to soon have recourse to stimulants. *Retention* of urine sometimes occurs, and must be instantly relieved by passing a gum-elastic catheter or the finger up the wound to the neck of the bladder. Warm fomentations and opiates will then allay pain and irritation. About the fourth or fifth day, the urine may suddenly cease to escape through the wound, and be discharged through the urethra;—the patient "wets," as nurses are accustomed to understand it. This, however, seems due to a temporary turgescence in the wound, resulting from inflammatory swelling which occludes the outlet; subsiding in a day or two, the urine again escapes by the wound. The same temporary discharge of urine through the natural passage may happen at an earlier period,—within twenty-four hours after operation. It is not at all a favourable sign. Urine having again returned through the wound, the quantity gradually diminishes during contraction and granulation, a portion coming away by the urethra; until the wound closes about the end of a fortnight to three weeks. The cure is completed in from thirty to forty days. In the case of a large mulberry calculus which I removed from a man sixty-five years of age, the patient returned sound to Hastings, at the end of a month. Phosphatic calculi generally entail the longest period for recovery after operation.

*Morbid conditions* of the wound, as that of sloughing or suppuration, must be treated accordingly.

*Urinary fistula* sometimes remains, with incontinence of urine, temporary or permanent. This result is met with mostly in children, and it generally ceases as age advances. Closure of the fistulous tract may perhaps be effected by occasionally passing a probe coated with nitrate of silver, or by the galvanic-wire cautery.

*Incontinence* alone may occur, particularly in childhood, if the patient be allowed to get up too soon, before the sphincter of the bladder has recovered its tone. *Impotency* sometimes results, from wound or injury

involving the ejaculatory ducts in the substance of the prostate. *Fæcal fistula* may be the result of a wound of the rectum; or of bruising of the bowel, either by a forcible use of the finger in the act of protecting it, or during extraction of the stone.

CAUSES OF DEATH, AND RESULTS, AFTER LATERAL LITHOTOMY.—The principal *causes of death* are:—(1) Age; (2) Large Calculus and Pelvic cellulitis; (3) Disease of the Kidneys; (4) Hæmorrhage; (5) Shock; (6) Cystitis; (7) Peritonitis; (8) Pyæmia.

(1) Age has a remarkable relation to the mortality after lithotomy. The lateral operation is rarely fatal in childhood; a dangerous operation, in middle life; and a perilous or fatal operation, in old age. This operation has been found to be four times as fatal in adults as in children, at the Norwich and Norfolk Hospital. Cheselden lost only 1 patient out of 35 under ten years of age; and of the cases recorded by Mr. South (in Chelius) as having been operated on at St. Thomas's Hospital during a period of twenty-three years, the mortality, at that period of life, was only 1 in 58. Coulson's table of 2972 cases shows an increasing mortality at each successive decennial period:—under ten years, it is 1 in 13; it thence gradually rises, after ten to eighty years; to 1 in 9, 1 in 6, 1 in 5, 1 in 4, 1 in 3·65, 1 in 3·23, 1 in 2·71. The mortality at *all ages*, rates at 1 in 9, according to the St. Thomas's table of 125 cases where the age was stated; but in 1827 cases, collected by Sir H. Thompson from the Metropolitan and Provincial Hospitals, the average mortality was higher,—nearly 1 in 8; and in Coulson's general table of 6505 cases, male and female, the average mortality rises still higher,—to 1 in 6·56, or about 2 in every 13 cases.

(2) *Size of the Stone*.—A large stone is far more dangerous than a small one, in regard to the result of operation; and the danger increases with the size; or *weight*, of the stone. This may be due, either to bruising and laceration of the neck of the bladder, or to infiltration of urine and pelvic cellulitis; as the result of forcible extraction. Crosse's table of 704 cases, in the Norwich Hospital, shows the increasing danger according to the size of the calculus, estimated by its weight. When the weight of the stone was under 1 ounce, the deaths were in the proportion of 1 in 11·25 cases; from 1 to 2 ounces, 1 death in 6·61 cases; from 2 to 3 ounces, 1 in 2·18; from three to four ounces, 1 in 1·57; and from 4 to 5 ounces, 1 in 1·66 cases. The chance—observes Mr. Coulson—which a patient has for recovery after lithotomy can, therefore, be calculated beforehand, and independent of every other consideration, from the ascertained dimensions or weight of the stone.

(3) *Disease of the kidneys*.—Chronic pyelitis, or chronic nephritis resulting in degeneration of the kidneys with albuminous urine, may be said to represent that diseased condition of the kidneys which is most prejudicial to recovery after lithotomy.

In estimating the comparative mortality of lithotomy in *adults* and *children*, two elements seem to be in favour of the latter;—at an early period of life, the kidneys are usually sound, and the stone of small size,—thus entailing less liability to injury of the neck of the bladder, or to infiltration of urine followed by pelvic cellulitis.

In children, death generally results from some accidental violence; as the formation of a false-bladder in the recto-vesical space, or disruption of the neck of the bladder from the membranous urethra. In adults, however skilfully the operation may have been performed, the

state of the kidneys and the size of the stone may severally lead to a fatal issue.

(4) *Hæmorrhage* may occur primarily, or secondarily after the operation; in the latter case it takes place in about a week, or ten days, or even a fortnight. Primary hæmorrhage is rarely fatal; in Liston's experience, one such case happened in 100 operations; and Coulson has not experienced dangerous hæmorrhage frequently; but in France, Begin affirms that it is the cause of death in 1 out of every 4 deaths, and Boyer regards hæmorrhage as one of the chief dangers of lithotomy.

(5) *Shock*, as the cause of death is very uncommon; and it generally happens in old people.

(6) *Cystitis* is also a rare cause of mortality; although Boyer attributes three-fourths of the deaths after lithotomy to this cause, or its consequences by extension to the kidney or peritoneum.

(7) *Peritonitis*, as a consequence of cystitis or pelvic cellulitis, may thus cause death; but peritonitis *per se*, is a rare occurrence, especially in adults.

(8) *Pyæmia* may be consequent on peritonitis; but it more frequently arises from inflammation of the prostatic plexus of veins, and generally in old persons, at the end of a week or fortnight.

In estimating the results of lithotomy, no Surgeon should judge from his own experience of a *limited* number of successful cases, in succession. I, for instance, have not yet lost a case; and Surgeons of very extensive experience are well aware of the fallacy of these serial cases. It has been truly said that "ten, twenty, thirty cases may succeed without interruption, and the operator flatters himself he is never to lose a patient, when two or three deaths follow in quick succession, and reduce him to a level with his neighbours, or at least within the limits of variation which the analysis of a large number of cases indicates."

RECURRENCE OF STONE.—After the lateral operation of lithotomy, and after the median operation also, a second stone sometimes forms. The liability to this recurrence, of calculus, and its relation to various circumstances, has been statistically investigated by Mr. C. Williams, House-Surgeon at the Norfolk and Norwich Hospital. From the opening of the Hospital in 1772 to November 1863, or during a period of ninety-one years, 923 cases of stone in the bladder underwent some form of lithotomy, excluding 2 cases of lithotritry; of these, 24 suffered a relapse, and underwent a second operation. The proportion of such cases to the whole number of stone-patients is 1 in 38·45. Of the 24 cases of recurrence, and a second operation of lithotomy; 19 were cured, and 5 died; 3 had stone a *third* time, 2 of which were cut and recovered, the third was deemed unfit for operation. All the patients were males, no instance having shown itself of recurrence in the female. In respect to *age*;—6 of the cases were under ten years of age; 2 between ten and twenty; 1 between twenty and thirty; 4 between thirty and forty; 2 between forty and fifty; 2 between fifty and sixty; and 7 between sixty and seventy. One death occurred below forty years of age; and four above that period of life. The *period* of recurrence varied from one year to twelve years; the average period was thirty-three months. *Lateral* lithotomy was performed in all the cases, excepting 8; 2 of which were cut on both occasions by the median operation, and in 4 this operation was resorted to on the second occasion. In 14, the calculi were removed in a perfect and entire condition at the first operation; while in 8, the calculi were broken in the extraction; in 1 the

stones were very small and numerous; and in the remaining 1, a sacculated stone was left undetected in the bladder. The nature of the second calculus was not in all cases the same as that of the first; in 16, the second formation had the same composition as the first, 9 of which were phosphatic while 7 consisted of lithic acid and the lithates; the phosphates succeeded the lithates in 5, and the oxalates in 2 cases.

**MEDIAN LITHOTOMY.**—The median operation of lithotomy is so named, because the incision is made in the *middle line* of the perineum. But this operation comprises two methods of procedure in relation to the *prostate*; a vertical section of the membranous urethra alone, and then dilatation of the prostate with the neck of the bladder,—“*lithectasy*” in the male, as it might be termed; or a vertical section of the prostate, as well as of the membranous urethra. Formerly the one was called also the “*Marian operation*,” as having been advocated by Sanctus Marianus; and the “*operation of the apparatus major*” from the number of instruments employed in performing it.

*The Old Marian Operation.*—A grooved staff was introduced into the bladder, and the patient trussed up as for lateral lithotomy; the operator then made a vertical and nearly central incision, just to the left of the raphé, and terminating just above the anus. The *membranous urethra* was opened in the groove of the staff, and the knife being kept well in the groove, a long probe was passed by the side of the knife into the bladder. Both staff and knife were then withdrawn, leaving only the probe as a guide to the bladder. Along this instrument two iron rods or “*conductors*” were introduced, and by separating their handles, the prostate and neck of the bladder were dilated,—or as John Bell observes, the operator “*tore open the prostate*.” The *conductors* were held aside, and “*dilators*” introduced to make way for the forceps, wherewith the stone was extracted. Thus, as Le Cat expressed it, the two principles of the Marian operation were; “*small incision, much dilatation*.” Vacca revived the median operation, and practised also a vertical section of the *prostate*; thereby avoiding laceration of this part, but endangering the rectum.

*Allarton's Operation.*—The Marian Operation had long fallen into disuse, but of late years it has been revived and slightly modified by Mr. Allarton; and with his name Median lithotomy is now generally associated, in this country.

The operation is performed much in the same way as by the old Marian operation, up to the introduction of the probe into the bladder; when the *fore-finger*, instead of dilators, is introduced along the probe, and with a semi-rotary motion, the prostate is thus dilated. The points to be attended to are these:—the curved staff is held by an assistant, firmly, perpendicularly, and hooked up against the pubes; the fore-finger of the left hand is introduced into the rectum, so that its point shall steady the staff in the prostate; a straight, sharp-pointed knife is entered into the perineum, in the *middle line*, about half an inch above the anus, and carried on steadily till it strikes the groove of the staff at the membranous urethra in front of the prostate,—a depth of about one inch and a half; the knife is moved along the groove towards the bladder for a few lines deeper, and then withdrawn, at the same time cutting upwards an external incision of  $\frac{3}{4}$  to  $1\frac{1}{2}$  inches, according to the presumed size of the stone. A long ball-pointed probe is slid along the groove of the staff into the bladder, and the latter instrument then withdrawn, as in the old Marian

Operation. But the left fore-finger is passed along the probe into the bladder, and used to dilate the prostate and neck, serving also as a guide to the forceps. When the stone is free, it comes at once into contact with the finger, and, if of moderate size, passes readily into the wound on withdrawing the finger; the patient having power to strain upon and thereby facilitate the extraction of the stone.

The advantages claimed for the median, over the lateral operation, are; that the incision being strictly in the median line, no muscles are divided, and no gaping open wound is left; the integrity of the bladder being preserved, and no chloroform given, the patient himself helps to expel the stone. This operation is most suitable for *small* stones.

The *results* of Median, as compared with those of Lateral Lithotomy are decidedly unfavourable; a difference owing doubtless to the fact, that in median lithotomy, without section of the prostate, this gland and the neck of the bladder are bruised and lacerated by the dilatation,—whether with “dilators” or the “fore-finger.” Thus, comparing the results of 44 cases of median lithotomy with the last 44 current cases of lateral lithotomy in the Norwich Hospital, 1863; Mr. Williams’s table shows that of the median cases, 11 died, whereas of the lateral cases, only 2 died. The average period of recovery was seven days in favour of the median operation, thirty days instead of thirty-seven.

*Rectangular Staff Operation.*—Dr. Buchanan of Glasgow introduced this procedure, which is a modification of the median operation. He uses a rectangular staff, with the short branch grooved at its side. This instrument having been passed into the bladder; the angle is made to correspond in situation with the front of the prostate, the lower or grooved branch lying parallel to the rectum. The left fore-finger is passed into the rectum, and a long straight knife, held with the blade horizontal and the edge turned to the left, is made to enter the perineum opposite the angle of the staff and passed straight into and along the groove, into the bladder. The membranous urethra is thus left *untouched*. In withdrawing the knife, a lateral section of the prostate is made, in its left lobe; and at the same time, an external incision downwards and outwards, round the upper and left side of the anus, to about  $1\frac{1}{4}$  inches in extent.

Certain features in this operation are adduced in its favour:—the more direct line to the prostate, which, at the angle of the staff, is situated close to the surface of the perineum; the membranous portion of the urethra is avoided; all blood-vessels are out of the way, and consequently there is no important hæmorrhage; the rectum is less liable to be wounded; and there is less risk of deep-seated infiltration of urine.

*BILATERAL LITHOTOMY.*—Dupuytren’s operation consisted in making a semilunar incision, transversely, in front of the anus; the convexity of this incision being upwards, and the horns extending laterally to between the anus and the tuberosity of the ischium on either side. The tissues were carefully divided upwards to the membranous urethra, avoiding the rectum; this portion of the urethra was opened by a median incision from before backwards, with a double-edged bistoury; then, the curved double lithotome was passed along the groove of the staff into the bladder, the staff withdrawn, and the concavity of the lithotome being directed downwards, the blades were opened, and, in withdrawing the instrument, both sides of the prostate were divided obliquely downwards and outwards to the requisite extent. The extraction of the stone is then accomplished in the usual manner.

The results of this operation are unfavourable; 19 deaths having occurred in 85 cases, or 1 in  $4\frac{1}{2}$  cases.

*Medio-bilateral Operation.*—Civiale, in 1836, modified the median operation by his medio-bilateral procedure. It consisted of a median perineal incision, followed by a transverse section of the prostate with a straight double-bladed lithotome, which was passed into the bladder through the membranous urethra, along the groove of the staff, and the blades withdrawn open.

QUADRILATERAL SECTION OF THE PROSTATE has been recommended by Vidal de Cassis, in cases of *large* stone; no matter what the direction of external incision may be, so that it is not too small,—whether oblique, vertical, transverse, or curved. The principles of this operation are; to have one large external incision, and many small internal ones. The two first sections of the prostate are made along the inferior oblique diameter of the gland on either side, which will prove sufficient when the stone is of moderate size; but, two superior oblique sections must be added, first one and then the other, when the stone is large.

RECTO-VESICAL OPERATION.—Lithotomy through the rectum is claimed by Sanson as his procedure. A grooved curved-staff having been introduced into the bladder, a vertical incision is made, corresponding to the raphe of the perineum, and dividing the sphincter ani and lower part of the rectum. Continuing the dissection, the membranous portion of the urethra and prostate are exposed. A vertical section of the prostate is then effected; either by passing the knife along the groove of the staff from before backwards, or by entering the knife behind the prostate and drawing it forwards on the finger in the groove of the staff. A portion of the base of the bladder, uncovered by peritoneum behind the prostate, may even be divided. The staff is withdrawn, the finger introduced, and the stone extracted with the forceps.

This operation has been recommended on the ground of its affording an easy passage for extracting instruments, and as being free from the risk of hæmorrhage. But there is great risk of wounding the peritoneum and vesiculæ seminales; and of the subsequent occurrence of urinary infiltration, the passage of feces into the bladder and recto-vesical fistula. Coulson has seen cases of permanent fistulous communication. This method of lithotomy has, therefore, been discarded; and it cannot be deemed advisable even in cases of impacted calculus in the wall of the bladder.

The *results* are very unfavourable; in 185 cases thus operated on, 38 died, being a mortality of 1 in 4.86. And the subsequent condition of those who recovered is not stated.

SUPRA-PUBIC, HYPO-GASTRIC, OR HIGH OPERATION.—The *size* of the calculus, or the state of the *perineum*, especially with regard to the pelvic outlet, may render perineal lithotomy, in any form, impracticable. Under these circumstances, or other impracticable conditions, recourse may be had to supra-pubic lithotomy. In *children*, and persons below twenty years of age, the bladder stands high above the pubes, and presents a portion uncovered by peritoneum, which is freely accessible; under eight years, the peritoneal reflection from the bladder does not generally reach lower than one inch and a half to two inches from the navel. In *old* persons, especially when emaciated, the bladder lies deep in the pelvis, behind the symphysis pubis, and would be difficult to reach.

In order to perform supra-pubic lithotomy, the bladder must be made

to rise above the edge of the pubis; and this may be accomplished either by full distension of the bladder with water, or by means of a catheter or other instrument introduced through the urethra into the bladder, so that its point shall project above the pubes. Both means are adopted to ensure a presenting part or point of the bladder in that situation. The operation consists in making a vertical incision in the middle line, above the pubes, carried upwards to about three inches in length; the linea alba is exposed, and the incision carried through the muscular wall of the abdomen and fascia transversalis; the projecting part of the bladder, uncovered by peritoneum, is sought just above the symphysis, and opened on the point of the instrument within its cavity; this incision being prolonged downwards towards the neck of the bladder with a probe-pointed bistoury, sufficiently to admit the finger. The forceps is then passed in, and the stone extracted. Various instruments have been devised wherewith to puncture the bladder from within, when reached by the incision. Thus, the *sonde-à-darde* is a puncturing instrument, combining a trocar concealed in a catheter; and this is used by Civiale. The performance of this operation is much more difficult than it would appear to be.

The *after-treatment* is simple; urinary infiltration is prevented by placing the patient on his back, and it may perhaps be advisable to introduce a gum-elastic catheter into the bladder, leaving it there for a few days until union of the wound has taken place. Formerly, it was thought necessary to close the bladder by sutures; and even to make a counter-opening through the perineum into the membranous urethra or the neck of the bladder, with a view of securing a free drain for the urine. These complications are now entirely discarded, whenever the operation is occasionally resorted to.

The *results* of this operation are, however, singularly fatal. Professor Humphry of Cambridge has shown that in 104 cases, 31 were fatal, mostly in consequence of peritonitis and urinary infiltration; a mortality of 1 in 3·08. He had himself 1 successful case, and other Surgeons, especially M. Souberbielle and Dr. Carpenter of Pennsylvania, have also had occasionally a successful result. But it should be remembered that the operation is had recourse to when the stone is of unusually large size, and the lateral operation being inapplicable, the results of the two methods cannot fairly be compared.

**LITHOTRITY.** — The operation of breaking-down the stone in the bladder, so as to allow of its extraction, or discharge, by fragments through the urethra; was early devised and attempted, in some way, as a substitute for the cutting operation of lithotomy. This procedure was noticed by Hippocrates amongst the Greeks; by Albugenis of the Arabian school; by Franco, Guido de Cauliaco, Hildanus, Haller, and other authors down to the end of the last century. In 1813, Gruithuisen, a Bavarian Surgeon, published two memoirs on the subject; describing his instruments for the drilling or boring, and then crushing the fragments, of stone in the bladder. But these isolated and imperfect attempts failed to introduce Lithotritry into the Practice of Surgery. Civiale, in 1817, then a poor student, first succeeded in drawing attention to Lithotritry, by constructing certain boring instruments, which he brought before the notice of the French Minister; and continuing his labours in subsequent years, followed by Amussat in 1822, and Leroy d'Etiolles in 1823, this method of removing stone from the bladder acquired a recog-

nised and established reputation in France. Subsequently, in this country, the first *crushing* instrument of any value, was invented by Mr. Weiss, in 1824. It consisted of two blades, sliding one within the other, and worked by a screw at the handle. With a somewhat similar instrument, in 1825, Mr. Hodgson at the Birmingham Hospital, first performed the operation of crushing stone in the bladder. Heurteloup in 1830, and Costello afterwards, devised an instrument for hammering the stone to pieces; but the crushing procedure prevailed, and was mainly brought into practice by Sir B. Brodie. It is also worthy of record, that the oval slit in the under or female blade for the escape of detritus, in using

FIG. 443.

the lithotrite, was suggested by Mr. Oldham, a gentleman connected with the Bank of England. Since the period referred to, lithotrity has received the special attention of Coulson, Sir W. Fergusson, Skey, and Sir H. Thompson. The latter Surgeon may justly be entitled the champion authority respecting this operation, he having presented the results of his extensive experience in *An Analysis of 181 Consecutive Cases of Stone in the Bladder of the Adult, treated by Lithotrity.* (Med.-Chir. Trans., 1870.)

The *Lithotrite*, or instrument for crushing the stone, now generally

FIG. 444.

used is Weiss's "newly-invented Lithotrite," or Sir Henry Thompson's admirable lithotrite. It enables the operator to exercise powerful, yet nicely regulated screw-pressure; its cylindrical and finely fluted handle aids the sense of touch; and the whole is a light and delicate instrument. The handle, slightly modified, as used by Sir William Fergusson, is here represented. (Fig. 443.) Another form of instrument

is also used by the latter distinguished operator,—a rack and key lithotrite (Fig. 444); but which is I believe less generally used. I prefer a screw instrument, and especially Thompson's lithotrite, for the three reasons just stated. The fenestrum or oval aperture in the under blade (Fig. 445), is of great importance, as already stated; Civiale's lithotrite

FIG. 445.

(Fig. 446), having no aperture in the female blade, may be used for crushing fragments of stone. A steel sound, for detecting fragments, is also very serviceable; and an injecting apparatus

FIG. 446.

will be required, consisting of large-eyed catheters of different sizes, and a strong, large-sized brass syringe, the nozzle of which fits the catheters.

*Preparation of the Patient for Lithotrity.*—Prior to any operation for breaking-up a stone in the bladder, it is absolutely necessary that not only should the general health be attended to, but that the bladder more especially should be brought into as quiet a condition as possible. Freedom from vesical irritability or inflammation is more important in relation to lithotrity than to lithotomy; the former operation being perhaps an unavoidably more prolonged procedure within the bladder, a repeated operation, and one which leaves fragments of stone behind as a continued source of irritation during their discharge. Hence, if the bladder or kidneys be diseased, lithotrity should be postponed or abandoned.

*Lithotrity* is thus performed:—The patient having been placed recumbent on a bed or couch of convenient height; the pelvis should be slightly raised on an unyielding pillow so as to bring the lower fundus of the bladder in a line with the urethral orifice; the head and shoulders should be supported by pillows, and the legs separated and somewhat flexed. Chloroform may, or may not, be administered. Civiale and Sir B. Brodie were both averse to its anæsthetic influence, alleging that the feelings of the patient are a safe guide in two essential matters; as to whether any injury is being inflicted on the bladder, and whether the operative proceeding is continued beyond what the bladder and constitution are capable of enduring. But, assuming a due manipulative skill in using the lithotrite; the irritable state of the bladder, and a nervous, restless state of the patient, in many cases, will as often render the influence of chloroform an invaluable or indispensable adjunct in performing lithotrity. The bladder is first emptied, and then injected with tepid water until it contains about five to seven ounces of fluid; in order that its cavity shall be sufficiently distended to remove the mucous membrane from the blades of the lithotrite in seeking the stone, and to make room for crushing without injuring the bladder by splintering. In old cases of stone, the bladder may be so thickened and irritable as to eject a few spoonfuls of fluid; then the injection must be repeated very slowly, and gradually, pausing occasionally until the bladder becomes accustomed to the increasing distension. On no account without sufficient dilatation of the bladder should the operation be proceeded with. Then, the Surgeon, standing on the right side of the patient, as the most convenient position, introduces the oiled lithotrite cautiously, along the urethra. The abrupt curve of this instrument, unlike the arched curve of the catheter, and resembling that of a sound, must be remembered as soon as the instrument reaches the curved portion of the urethra. By depressing the handle slowly down to a right angle with the perineum, the end of the lithotrite is brought into the direction of the canal under the pubic arch, and thence passed gently into the bladder. A slight rotatory movement with the instrument will always indicate when it has entered the bladder.

*Seizure of the stone* may be effected in either of two ways; by making it *fall* into the blades of the lithotrite, or by *searching* for it in a certain manner.

Sir B. Brodie recommends that the instrument should be raised, the blades opened, and that the convex extremity of the under or female blade should be rested against the lower fundus of the bladder, and gently pressed down, so as to make a conical *depression* in this situation; into which the stone falls by its own weight, or by a slight shake or jerk of the instrument with the hand. Similarly, Mr. Skey gives a smart blow with the open hand against the pelvis of the patient, a *coup*, he says,

which will succeed again and again in making the stone fall into the grasp of the lithotrite. The male branch is pushed forwards to seize the stone. This manœuvre may have to be repeated several times before the stone is securely caught; the female branch remaining stationary, while the male branch is slid a little up and down alternately, until the stone is seized. Civiale recommends another method, in principle, as Sir H. Thompson observes, the reverse of the preceding. By position of the patient, the centre of the bladder and space beneath it are selected as the area of operation; *no depression* is made; contact between the walls of the bladder and the instrument is, as much as possible, avoided. The instrument is applied to the stone in the situation which it naturally takes, and the operator carefully avoids moving it, or any movements of concussion whatever, however slight.

The *situation* of the stone is often ascertained in *passing* the lithotrite; then, the blades are inclined slightly away from the side on which the stone lies, carrying the instrument backwards also towards the posterior wall of the bladder, while the male blade is slowly withdrawn, not to impinge on the neck of the bladder. Turning the opened lithotrite over towards the stone, and slowly closing the blades, the stone will almost certainly be seized (Fig. 447.) Most frequently the stone will be caught on the

FIG. 447.

right side of the floor of the bladder. If no stone be felt on entering the bladder, its cavity is *explored*; first, without altering the axis of the shaft of the instrument from its central or vertical position, by simply inclining the open blades to the right side, and then to the left side; finding no stone; secondly, depress the handle of the instrument about half an inch, thereby raising the open blades slightly from the floor of the pelvis to a horizontal plane, and turn them to the right and left. In completing each of these movements, the blades are closed to seize the stone. These five positions—vertical, right and left incline, right and left horizontal, will explore the bladder fully—middle, right and left, and will thus almost certainly find any stone of moderate size in a healthy bladder. If the prostate be enlarged, and the stone possibly lodged in a depression behind

it; or if the latter is small, or a fragment only, the blades may be reversed or turned downwards, when the stone will often be found and secured with ease.

The object of this method is strictly to avoid giving any jerk to the instrument or to the bladder; and by barely coming in contact with its interior, no pain or contraction of the bladder is provoked. The same object was sought to be attained by the other method, simply by *not moving* the instrument in the bladder for the purpose of exploring to ascertain the situation of the stone; but by resting the instrument in contact with the interior of the bladder, to make the stone fall into its blades.

Coulson seems to combine *both* these methods in using the lithotrite; a slow twirling revolution of the instrument on its own axis, between the thumb and finger, without changing its central direction; and at the same time, a gentle sliding motion of the male branch backwards and forwards to the extent of half or three-quarters of an inch—thus gently raking or traversing the floor of the bladder on either side successively.

Of these three methods of using the lithotrite, I prefer the latter.

*Crushing the Stone.*—When once firmly fixed between the blades of the lithotrite, the stone is to be crushed into fragments. It is raised to the centre of the bladder, so that the mucous membrane shall not be injured by the splintering of the stone. (Fig. 448). Crushing may first

FIG. 448.

be attempted by pressure with the hand alone, without the action of the screw. The female branch is held firmly by the left hand, applied to the square portion; the circular projection immediately behind is embraced between the index and middle fingers of the right hand, hooked on to it and used as a point of resistance; the expanded extremity or wheel of the male branch rests in the palm of the same hand turned upwards and forwards. In this position, by strongly and repeatedly contracting the fingers towards the palm, the male branch is slowly and cautiously driven forwards on the stone, which is distinctly felt to break-down. A small stone may thus be easily crushed. When this manipulation fails, the screw must be brought into action. Still holding the female branch firmly with the left hand, the handle of the screw is held between the thumb and fingers of the right hand, and the screw worked gradually from left to right; thus propelling the male branch forwards on the stone. If the key-handled (screw) lithotrite be used, the handle is held between the

fingers of the right hand, backwards, as in drawing a cork with a cork-screw; and worked also by a number of short and sharp turns of the wrist. The annexed figure shows the instrument in action, as held and worked by Sir William Fergusson, in recent years. (Fig. 449.)

In either mode of crushing, by hand-pressure or screw-pressure, the male branch must be sent home into the female branch, so that the blades

FIG. 449.

come together. This object is known to be attained by observing that the entire length of the screw passes down the lithotrite. Then the instrument can be safely withdrawn.

The fragments must be got out of the bladder as soon as possible, but not by a prolonged use of the instrument; lest in removing one source of irritation and inflammation, another be substituted. The crushing should not be repeated, unless the stone is small and friable and can easily be reduced at once. This first sitting should be short, not exceeding five minutes.

Detritus can be removed amounting to a considerable quantity, and containing some not insignificant fragments. For this purpose, the bladder should be washed out with tepid water, injected through a large-sized and large-eyed catheter. By repeating the injection three or four times, the fluid drawn off at last ceases to contain any detritus. Sir H. Thompson, usually, does not wash out the bladder.

*After-treatment.*—The patient should lie in bed, recumbent, for twenty-four hours, and not be allowed to stand or stoop forward in passing water, lest fragments might fall against or lodge on the neck of the bladder, greatly increasing the risk of irritation. Diluent drinks will promote the discharge of the detritus. In elderly persons with enlarged prostate, Sir B. Brodie recommends that the bladder should be washed out daily.

Subsequent sittings will be required to crush the fragments. Intervals of from three days to a week should elapse; when the operation may perhaps be prolonged to ten minutes at a time, as the bladder becomes accustomed to the instrument, or its irritability subsides with the gradual removal of the calculus. Generally from three to six sittings must be allowed, before all the fragments can be safely crushed.

In performing these after-crushings, Civiale's lithotrite with no slit in the female blade, is very serviceable for breaking-down and removing fragments; the instrument being withdrawn charged with more than detritus. Fragments of rather large size may thus be extracted safely through the urethra. Having seized a fragment, the size of which may be estimated by observing the separation of the blades as indicated by the length of screw exposed at the handle of the instrument, the fragment is

drawn to the neck of the bladder; when by a sort of slight pulling jerk with the instrument, the practicability of easily extracting it through the urethra can be ascertained. The bladder is washed out, to remove smaller particles. This procedure of fragment-extraction I have seen practised by Sir W. Fergusson. It seems preferable, however, to crush all fragments, and allow the detritus to escape per urethram; according to the method of Sir H. Thompson.

A *final* exploration of the bladder is made to determine the complete removal of every fragment; any one remaining portion would form the nucleus of a recurrent calculus.

Certain *difficulties* are liable to occur in the performance of lithotripsy. They may be sufficiently anticipated and overcome by due attention to the directions given respecting the operation. Excessive sensibility and irritability of the bladder, enlargement of the prostate, and the impaction of angular fragments of stone in the urethra; may thus severally be managed.

*Dangers of Lithotripsy.*—These are referable to the state of the bladder and kidneys, induced by the operation.

*Hæmorrhage* happens, sometimes, to an inconvenient amount for the free working of the instrument; though rarely to a dangerous extent. In the 115 cases operated on by Sir B. Brodie, he did not meet a single example of serious loss of blood from the urinary organs. It was, however, so copious as to necessitate immediate recourse to lithotomy, in a case operated on by Mr. Key; and a patient at the Hôtel Dieu, in 1832, died of hæmorrhage from the bladder.

*Cystitis*, acute, or more frequently chronic, ensues in some cases. This is usually the consequence of prolonged lithotripsy.

*Atony of the bladder*, occurs chiefly in old persons. The patient enjoys too quiet a state of the bladder after operation, the urine being retained with ease for several hours, owing to the loss of expulsive power. Chronic cystitis is very apt to supervene by retention of urine, in this deceitfully tolerant state of the bladder.

*Spasmodic* retention of urine sometimes follows the operation, and it occurs mostly in combination with an atonic state of the bladder. Both are most frequent in old persons, with enlargement of the prostate. The treatment of the spasmodic retention consists in giving a warm bath and then a full dose of opium. In either case, the urine must be drawn off with a large-sized catheter, rather than allow any accumulation in the bladder.

Retention from the impaction of coagula or a fragment in the neck of the bladder must be treated by catheterization.

*Suppression of Urine* is an occasional consequence of the operation, and probably depends on some previously existing latent disease of the kidneys.

The *constitutional disturbances* incident to lithotripsy may be comprised under rigors, and febrile attacks, including pyæmic infection. *Rigors* not unfrequently occur immediately after the operation, especially after the first sitting; and last perhaps for some hours. This attack is most common and severe when the operation has been prolonged, and not at all in proportion to the amount of pain. A full dose of opium, or a tumbler of warm brandy-and-water, as Sir B. Brodie recommended, are the best remedies; the patient lying in bed and wrapped in a blanket. Irritative *fever* may ensue, which rapidly assumes a typhoid character; the pulse rising in frequency to beyond what can be distinctly counted, and becoming proportionately feeble and irregular, with a dry hot skin, and dry, harsh, brown tongue. This attack is more surely fatal than the most

severe rigors. *Pyæmia* occasionally supervenes, probably in connexion with suppuration as the result of damage done to the bladder. Pre-existing disease of the kidneys attended with albuminous urine, always tends to induce these unfavourable or fatal constitutional consequences of lithotritry.

Their treatment mainly comprises the administration of opium and stimulants, judiciously regulated.

*Results of Lithotritry, and, as compared with Lithotomy.*—Unquestionably the accumulating results of experience in lithotritry lead to the conclusion that a far larger proportion of cases can fairly be submitted to this method of treatment than was formerly supposed, instead of to lithotomy. When first practised in this country, the results of Sir B. Brodie's 115 cases showed a mortality of somewhat less than 1 in 12½; whereas the mortality of lithotomy is about 1 in 7, or even as high as 1 in 4½. Civiale's cases of lithotritry in one year—1862, amounted to 45, about his annual average. Of these, 8 were partially cured; and the operation was successful in all the remaining 37, but 1. The same distinguished lithotritist states that his total mortality in 591 operations, was 14 deaths, or only 1 in 42.21. But this general result has been much criticized. Sir H. Thompson has been very successful; his cases having been more clearly recorded. From an Analysis of 184 consecutive cases of lithotritry in the adult; it appears that the recoveries, reckoning every kind of casualty following the operation, were 93 per cent.; but, omitting 5 cases of death from other causes, the mortality amounted to only 4 per cent. Mr. Crichton has performed lithotritry in 122 cases with only 8 deaths, or less than 1 in 15. Mr. Charles Hawkins has collected the results of all the cases of stone in the bladder admitted into the London Hospitals (excepting the Hospital for Stone), in the years 1862-63. The total number of patients was 177, comprising 86 children and 91 adults; of the whole number it would appear that only 32 were treated by lithotritry, while 139 underwent lithotomy—the remaining 6 cases not having been submitted to either operation.

Considering the relative mortality of the two operations—so highly in favour of lithotritry; the small proportion of cases submitted to this operation would scarcely seem judicious. At the Royal Free Hospital, it is true, the 7 cases of stone in the two years, all underwent lithotomy; but then they were all cases in children.

**SELECTION OF OPERATION.**—**LITHOTOMY OR LITHOTRITY.**—The practical importance of a judicious selection of cases for either operation is well enforced by Civiale's statistical results, in regard to all the calculous patients on whom he operated, in one way or the other, during a period of twenty years. The total number being 838 cases of stone in the bladder; only 548 were fit cases for lithotritry, 290, or more than one-third, were not operated on by this method; and of the last 332 cases included in this list, 241 were lithotritized, leaving 91 which were considered unfit for that operation. Of the 91 cases; 28 were lithotomized, and in 8 others the two operations were combined, making a total of 36 cases subjected to lithotomy; and of which, Civiale lost 18, or exactly one-half.

The *conditions* which determine the fitness or applicability of lithotritry, are:—(1) The state of the urinary organs, and of the bladder and kidneys in particular; (2) the general health of the patient, and as connected with age; (3) the nature of the calculus—as to size, density, shape, situation, and number.

When the bladder is healthy, and the kidneys free from disease, especially with regard to albuminous urine; the general health not deteriorated; and the stone small, and friable; all the conditions concur in favour of lithotripsy. The opposite conditions are, of course, unfavourable in a greater or lesser degree.

(1) The conditions of the *urinary organs* relate to the bladder, kidneys, prostate, and urethra. As more or less unfavourable may be mentioned; an irritable or inflammatory state or tendency of the bladder, or an atonic state, or an hypertrophied bladder of diminished capacity. The latter state is not unfrequently associated with extreme irritability of the bladder, thus further contracting its cavity. Chronic cystitis and especially of a purulent character, is a more unfavourable condition for operation, than acute cystitis; which is also comparatively rare. Disease of the kidneys of a nephritic or degenerative character, attended with morbid states of the urine, are specially unfavourable. Hence, casts of the tubes or blood in the urine, and the appearance of albumen to any extent, as persistent albuminuria, contra-indicate the performance of lithotripsy. Enlargement of the prostate is in *itself* only a mechanical objection to the operation; the stone often being lodged in a depression behind the enlarged gland, and not easily accessible to the lithotrite. Enlargement of the middle lobe more especially, diminishes the capacity of the bladder, deepens its floor, and tends to conceal the stone in a cavity behind the gland. But an enlarged state of the prostate is often associated with an unhealthy state of the bladder, and occurs mostly in advanced life. Stricture of the urethra, or an irritable state of the passage, will also obstruct the introduction of the lithotrite, and retard the discharge of detritus.

(2) The conditions of the *general health* which are unfavourable for lithotripsy, cannot be clearly defined; they comprise chiefly a deranged state of the digestive organs, with loss of flesh and strength; nervous depression; and recurring febrile attacks. But, in the 184 cases operated on by Sir H. Thompson, "many" of the patients were of "very feeble health and constitution."

*Age* is significant in its relation to the accompanying state of the bladder and the health of the patient. In *children*, the diameter of the urethra is small; the antero-posterior diameter of the bladder is short; the organ is irritable, and its neck is very dilatable, a peculiarity which favours the impaction of the fragments; while the indocility of the child is a great difficulty in performing lithotripsy, especially when repeated sittings are necessary. This latter difficulty can be overcome by chloroform; but the undeveloped condition of the genito-urinary organs before the age of puberty, renders the operation neither an easy nor a safe one. On the other hand, lithotomy is singularly successful. Nevertheless, if lithotripsy diminishes the mortality in adults, it should, as Mr. Coulson observes, have a still greater influence in reducing the comparative mortality when applied to children; in whom the urinary organs are in a healthy condition, and because the number of deaths in adults, after crushing the stone, is greatly increased by the state of the urinary organs at that period of life. Sir W. Fergusson, Mr. Curling, and other Surgeons in the London Hospitals, have performed lithotripsy in children, and with not unfavourable results. In *advanced periods of life* and old age, the irritable state of the genito-urinary organs forbids lithotripsy. Exceptional cases of successful results have been met with; Segalas having lithotripsy 14 octogenarians, without losing one; and 27 septuagenarians, with the loss of only two. Of

Sir H. Thompson's 184 cases; the mean age was no less than sixty-one years; forty-six were seventy years, and upwards; the oldest was eighty-four years; whereas, only three were below thirty years, and the youngest was twenty-two years old. Lithotomy, on the other hand, is very fatal in aged persons, and very successful in children.

(3) The *calculus* itself has an important influence with relation to lithotritry, more than to lithotomy. A *large* stone is unfavourable for crushing, owing to the number of fragments in the bladder and the continued discharge of detritus through the urethra, and the necessity for a more repeated performance of the operation. The bladder should be proportionately healthy, a condition not often co-existing with a large stone. From Sir H. Thompson's large experience, it appears that a stone about the size of a *date* or *small chestnut* (Fig. 450), and corresponding to somewhat less

FIG. 450.

than an *ounce* in weight; is always suitable for lithotritry; all stones of an ounce weight, and upward, being reserved for lithotomy. A stone of this size, and weight, may be easily discovered by sounding. In Sir H. Thompson's practice, lithotritry has never proved fatal, when the stone was no larger than a small nut; but, the rate of mortality corresponds with the increasing size of the stone, above that of a small chestnut. A *hard* stone yields sharp, angular fragments, very irritating to the bladder. A large and also hard stone may be said to contra-indicate lithotritry. But a soft or friable stone, even of large size, is not an unfavourable kind of calculus. Hence, the chemical nature of the calculus has some relation to lithotritry; certain uric acid calculi which ring when struck with the sound, and oxalate of lime or mulberry calculus, are not readily crushed; whereas phosphatic calculi are easily broken-down. The different consistence of the two latter kinds of calculi, in their relation to lithotritry, is however, a consideration more than counterbalanced by the state of the urinary organs; in the oxalic acid diathesis, these organs being comparatively healthy; in regard to phosphatic calculi, equally unhealthy.

The remaining peculiarities connected with stone in the bladder, present mechanical difficulties chiefly, as relating to the selection of the operation,—lithotritry or lithotomy. Thus, the *irregular shape* of a stone offers a difficulty in seizing it with the lithotrite. But similar difficulty is experienced in seizing with the lithotomy-forceps, and there is the additional difficulty of extraction. The *situation* of a stone may render it inaccessible; as when lodged in a pit behind an enlarged prostate, above the pubes, or encysted anywhere in the walls of the bladder. It may then be almost equally hard to get at in either operation. A *single* stone is more suited than several calculi to the performance of lithotritry, and

of lithotomy also. But the time necessary for the operative procedure of crushing must be taken into account. The presence of several calculi is not unfavourable for the operation of lithotripsy, provided only they be small and soft. Civiale has thus operated with success in a case where the bladder contained 40 calculi.

The *chemical composition* of calculi submitted to lithotripsy, has varied; all kinds of calculi having been crushed, but perhaps, chiefly those of uric acid and the urates. Thus, of Sir H. Thompson's cases; 122 were uric acid, and the urates; 16 were mixed; 40 phosphatic; 4 oxalate of lime; 1 pure phosphate of lime, and 1 cystic oxide.

RECURRENCE OF STONE.—After lithotripsy, a recurrence of calculus in the bladder is far more frequent than after lithotomy. In Civiale's practice, this has happened about once in every ten cases. Of 36 patients on whom he performed lithotripsy in 1860; 10 had been previously operated on, and stone had returned. But of Sir H. Thompson's 184 cases, a second operation for recurrence, was performed in only 13 cases. In no instance, however, was an operation of lithotripsy completed by lithotomy.

Recurrence must arise from some fragment having remained in the bladder, which formed the nucleus of another calculus. Hence, the practical importance of carefully searching the bladder at the last; the final exploration or sounding, to which I have already alluded. If a small fragment can escape detection in such practised hands as Civiale's, less experienced lithotritists should be far more guarded in completing a case.

Irritability of the bladder, remaining for a long time, is a not uncommon sequel of lithotripsy; itself successful. This never occurs after lithotomy; the bladder having been relieved of the stone, as the source of irritation, recovers its tone completely.

*Treatment.*—Whether after lithotripsy or lithotomy, a secondary calculus must be removed. Which kind of operation should be repeated,—crushing or extraction, must be determined by the conditions already mentioned with regard to the selection of these operative procedures. Secondary lithotomy may be performed through the track of the former wound; care being taken to avoid the rectum, which is somewhat drawn up and adherent to the membranous urethra and prostate. Right lateral lithotomy may be performed, as Liston suggested, provided the Surgeon be ambidextrous. The median operation offers an available resource in these cases.

PROSTATIC, and URETHRAL, CALCULI, are more conveniently noticed in connexion with Diseases of the Prostate Gland, and of the Urethra.

CALCULUS IN THE FEMALE.—Stone in the bladder is not of common occurrence in women, though not very rare. In 146 cases of stone operated on at St. Thomas's Hospital, during a period of twenty-three years; South states that 144 were males, and only 2 females, giving a proportion of 1 female to 72 males. This is greatly below the average. Crosse, at the Norwich Hospital found the proportion to be 1 female to 19 males. In France the average was higher; 1 to 22. But in Italy, Civiale finds the average to be 1 to 18; which may probably be taken to represent the general average. Coulson puts the proportion, among those who are submitted to operation, at about 1 female to 20 males. The probability is that stone forms more frequently, than it is found, in the female bladder. This seems owing to the peculiar anatomical conditions of the urethra, which facilitate the escape of a small calculus. The urethra is short, almost straight, of large size and readily dilatable, without any natural

contractions in the canal; and there is no prostate gland at the neck of the bladder. Thence, a stone may form in the bladder, but more easily escape through the urethra.

*Symptoms.*—In addition to the usual symptoms of stone in the male bladder, and the sure sign afforded by sounding; two special symptoms occur in the female. These are, bearing-down pains and pains along the urethra, and incontinence of urine,—a tendency to constant dribbling or wetting. Irritability of the bladder, from any of its various causes, or a vascular urethral tumour, may give rise to similar symptoms; but sounding will determine the diagnosis.

The consequences of persistent calculus are also peculiar; it may be discharged through the vagina, by an ulcerative communication through the bladder and the vagina, forming a vesico-vaginal fistula; or the stone may impede the descent of the foetal head in birth, as a rare cause of difficult parturition. I once saw an instance of this kind in the Royal Free Hospital; a woman died after child-birth, and a stone was found in the bladder, the size of a hen's egg, consisting of phosphates encrusted with carbonate of lime.

*Treatment.*—The various operative procedures for removing calculi from the female bladder, are of four kinds:—(1) Dilatation of the urethra; (2) Dilatation, with partial slitting up, of the urethra; (3) Lithotripsy; (4) Lithotomy, practised in four different ways.

*Dilatation of the urethra* may be accomplished rapidly, or slowly; the former method was recommended by Sir A. Cooper when the stone is *small* and that dilatation should be accomplished in a few minutes; but that when the stone is *large*, it will be better to dilate slowly and gradually from day to day, until the requisite extension is accomplished. Rapid dilatation is not much more painful than the slower; but, according to Dupuytren's experience, it is much more likely to be followed by *incontinence* of urine. Dilatation can be effected by various means; solid or flexible bougies, gum-elastic catheters, prepared sponge, or other tents; or by the cautious application of Weiss's female urethra dilator,—a two-bladed instrument, worked by a screw at the handle (Fig. 451), the speculum, or blunt gorget. After sufficient extension, a pair of forceps is introduced and the stone extracted. In one case I succeeded with forceps alone in extracting an oxalate of lime calculus, the size of an almond, which was impacted in the urethra of a young woman. The stone had been lodged there for some time, causing partial retention of urine; and when removed, its exposed surface was obviously "water-worn," by constant attrition of the stream of urine in micturition.

*Dilatation, with partial slitting-up of the urethra*, is an applicable procedure when the former method has been carried to the farthest

FIG. 451.

extent consistent with safety; and yet the stone is too large for extraction without thus dividing the urethra. This method is described by Ambrose Paré, who saw the elder Collot perform the operation. A grooved staff was introduced into the urethra, and on it a small incision was made vertically *upward*. Sir B. Brodie revived this operation, and divided the urethra directly upwards under the symphysis pubis. Dilatation was then made with Weiss's instruments, to a sufficient extent for the introduction of the forceps and extraction of the stone. The objection to the upward incision is that it necessitates extraction of the stone where the space is most restricted.

The *direction* of the incision has been varied by Surgeons; some cutting directly down, some obliquely down, and others sideways.

*Double* incision of the urethra, combined with dilatation, was proposed by Dionis; the urethral orifice being divided horizontally on both sides. In these operative procedures by urethral incision, the vagina is necessarily involved, when the incision is downwards, or even oblique. The probability of incontinence of urine resulting from the urethral incision, rather than from dilatation alone, seems doubtful; Surgeons of great experience holding directly opposite opinions on this important issue.

*Lithotrity* is preferable to either of the above methods, urethral dilatation, or with incision combined, when the stone is of *large* size. This operation is far more easily performed in the female than in the male; and it is frequently more successful in its results; both these advantages having reference to the peculiar anatomical conditions already mentioned.

*Lithotomy* is also more readily performed than in the male, and it may be done in either of *four* ways.

The patient is placed under chloroform, and tied up in the position as for the operation in males; and a grooved staff is introduced into the urethra, which is hooked up perpendicularly under the symphysis pubis. A common bistoury, lithotomy-forceps, and scoop, are the only other instruments required.

(1) *Urethral* lithotomy is nothing more than incision of the urethra, carried up the passage, so as to divide also the *neck* of the bladder. Dilatation is then made sufficiently to allow of the completion of the operation, by extraction. The *lateral* operation,—analogous to that in the male, is most frequently performed. A straight staff having been introduced into the bladder, its groove is directed downwards and outwards towards the ramus of the ischium, and the urethra divided obliquely downwards with a probe-pointed bistoury. This incision often intersects a small portion of the anterior wall of the vagina. Chelius has recommended a vertical incision directly downwards, thus dividing also the corresponding wall of the vagina. A bilateral section of the urethra has also been performed. Liston notched the neck of the bladder on both sides towards each ramus of the pubes, and then dilated for a few minutes until the finger could pass into its cavity.

(2) *Direct* lithotomy has also been performed, as suggested by Celsus. This method of “cutting on the gripe” in women, consists in passing the fingers into the vagina, in order to press the stone forwards against the neck of the bladder, and then making a transverse incision directly on the stone between the urethra and symphysis pubis. Lisfranc endeavoured to revive this method, in 1823; but it has justly fallen into disuse.

(3) *Vagino-vesical* lithotomy consists simply in making an incision through the vagina into the bladder, and thence extracting the calculus.

A curved staff is used so that its convexity shall appear in the anterior wall of the vagina, while the posterior is depressed with a blunt gorget or a speculum. In this method of operation the urethra is avoided, and afterwards a female catheter is introduced through this passage into the bladder, and the edges of the vaginal incision are brought together by suture. Vidal has thus operated in 30 cases without any death; there is generally no hæmorrhage, nor subsequent peritonitis; but vesico-vaginal fistula is a common result.

Incontinence of urine is apt to follow all these operations of lithotomy.

(4) *Supra-pubic* lithotomy has been recommended in the female, as an occasional resource.

SOLUTION OF STONE in the bladder has been proposed and tried by means of various solvent agents; taken internally, or injected into the bladder.

Of the *constitutional* remedies, alkalies chiefly have been tried; such as liquor potassæ, the bicarbonates of soda and potash, and the borate of soda. The Vichy and other mineral waters have been resorted to as solvent remedies. On the other hand, acids have been administered to dissolve certain calculi. Thus, uric acid calculus might yield under the influence of alkalies; while oxalate of lime, and the phosphatic calculi, would perhaps be amenable to the mineral acids, nitric and hydrochloric. These supposed remedies have been taken diluted during a prolonged course of treatment, but with little or no effect, otherwise than the relief of calculous symptoms. Their efficacy as “lithontriptics,” seems very doubtful.

The *injection* into the bladder of diluted alkaline or acid solutions, has also been tried; and with more successful lithontriptic effect. Unfortunately, however, the solution if strong enough to be of any use, endangers the coats of the bladder; and when sufficiently diluted to avoid this danger, any solvent action on the stone is very uncertain. Injection has proved most effectual in regard to phosphatic calculi; Sir B. Brodie having shown that they may be greatly reduced in size, or dissolved entirely, by means of a weak solution of nitric acid,—two or two and a half minims of strong acid to the ounce of distilled water. Dr. Hoskins employed a weak solution of acetate of lead,—one grain to the ounce, with a mere trace of free acid.

*Electrolysis*, or the dissolution of stone in the bladder, by the transmission of an electric or galvanic current, has had its advocates. Sir W. B. O'Shaughnessy, Dr. Bence Jones, Dr. L. Melicher, and Gruithuisen, have severally attempted this method of treatment.

---

## CHAPTER LVIII.

### DISEASES OF THE BLADDER.

THE Bladder is liable to Diseases, not differing in their nature from those of other organs; but which present modifications in their pathology and symptoms, and thence in their treatment. Thus, inflammation known as Cystitis, acute and chronic, and various Morbid Growths or Tumours, may

affect the bladder; but the Malformations of this organ are peculiar; and its Functional Conditions are partly special in their character; such as frequent micturition, retention of urine, incontinence or involuntary escape of urine, and engorgement with overflow of urine. These conditions may also be symptomatic of the diseases referred to, which involve structural alterations in the bladder.

*CYSTITIS—Acute.—Structural condition.*—The seat of inflammation affecting the bladder is primarily the mucous membrane; occasionally, in consequence of the intensity or duration of the process, the sub cellular tissue and the muscular or middle coat may secondarily become involved; but the inflammation never occurs in the middle, and outer or peritoneal investment, independently of the mucous membrane. The portion of this membrane situated about the neck of the bladder, is most commonly and severely affected; extending thence to the whole of the lining membrane. After death, the membrane is found injected and reddened in specks and patches; or it may have assumed a greenish slate colour, or a chocolate tint, when the inflammatory condition has been of some duration. Occasionally, lymph-effusion takes place on the surface of the mucous membrane; forming shreds or patches of lymph, or even a false membrane slightly adherent to the whole interior of the bladder. Very rarely, this membrane has been known to cause retention of urine, necessitating puncture of the bladder; and I remember the late Dr. Robert Knox to have told me that, in Edinburgh, he had seen a membranous vesical cast of this kind drawn out of the bladder by supra-pubic puncture. In the female, it is sometimes thrown off entire.

*Symptoms.*—The essential symptoms of acute cystitis are:—severe pain and sense of aching weight in the region of the bladder above the pubes, extending down the urethra into the perineum and down the thighs; this pain is accompanied by a frequent, urgent and soon intolerable desire to pass the urine, which is expelled at short intervals, in small quantities, by spasmodic straining efforts. These symptoms are those of simple irritability of the bladder, in an extreme degree. But the contracted bladder, forming a small, round, and firm tumour, is exceedingly painful on slight pressure over the pubes, or when touched or tilted with the finger through the rectum; and the character of the urine also,—high coloured and acid, mixed with mucus or pus, and perhaps tinged with blood, indicates an inflamed state of the vesical mucous membrane. The symptomatic inflammatory fever or constitutional disorder is often severe.

Cystitis usually commences suddenly and runs a rapid course; or it may supervene on the chronic form of the disease.

*Causes.*—Acute cystitis is commonly the consequence of an extension of inflammation from adjacent parts; most frequently from the urethral mucous membrane, by gonorrhœal inflammation extending backwards to the neck of the bladder, in retrocedent gonorrhœa, or more severe inflammation may have extended from the prostate, the rectum, or the kidneys. Injuries, such as blows and pelvic fractures, operations of lithotrity, prolonged catheterism, injections, and lithotomy; in the female, prolonged and instrumental labours; also the mechanical irritation of calculus; the chemical action of cantharides, and of some mineral poisons, and strong diuretics; or the action of the urine itself, retained and decomposed, as in stricture and prostatic enlargement. The disease arises also occasionally from gout, or from exposure to cold.

*Terminations.*—Resolution; or the disease may subside into the

chronic form; suppuration in the wall of the bladder, leading to peritonitis, or between the bladder and rectum, followed by urinary infiltration in the cellular tissue of the pelvis or of the perineum; ulceration, or gangrene of the mucous membrane, in the worst cases.

*Treatment.*—Remedial measures consist in derivation, diluents, and alkalies to render the urine unirritating, and the influence of opium. Thus, perfect rest in the recumbent position will relieve the bladder of the whole weight of the upward column of blood; while leeches, warm fomentations and hip-baths, will aid this derivation. Laxative aperients, such as castor-oil, preceded by a dose of calomel at the beginning, will also derive from the bladder and keep the bowels free from irritation. Diluent drinks, such as barley-water, should be liberally allowed; and the citrate or nitrate of potash, largely diluted. Opium may be advantageously administered in the form of enemata, or suppository, thus allaying the distressing vesical irritability; while the continued influence of opium taken internally, tends to subdue pain and inflammation.

If cystitis be the consequence of *retrocedent gonorrhœa*, the return of urethral discharge should be solicited by warm fomentations to the penis or wrapping it in a poultice. When the urine is acid, and its sediment yellowish and not coherent but purulent; Sir B. Brodie recommends a pill of calomel, two grains with half a grain of opium, to be taken twice or three times a day. When the urine is alkaline, and presents a small quantity of brownish adhesive mucus; the same authority advises the vinum colchici to be given in fifteen minim doses, thrice daily for three or four successive days.

Cystitis resulting from *cantharides* locally or internally absorbed, comes on usually within two to four hours after the dose; the symptoms soon reach their maximum of intensity, and subside in from six to twelve hours. Bicarbonate of potash and full doses of hyoscyamus, should be given every half-hour for three or four hours, and perfect rest enjoined. If a blister has been the cause, it must be removed at once, and the surface thoroughly sponged free of every particle of cantharides.

*Chronic cystitis.*—This form of the disease presents two varieties; inflammation of the vesical mucous membrane, with very slightly increased secretion, or with an abundant secretion of muco purulent matter. The one condition is *simple* chronic cystitis; the other is known as *catarrh* of the bladder or cystorrhœa. In both varieties, especially the catarrhal, the mucous membrane has become thickened, velvety, and of a dark colour; the vessels being injected or congested, and the muscular coat somewhat hypertrophied.

*Symptoms.*—The same symptoms are presented in both states of chronic inflammation; and modified only in degree from those of acute inflammation. But chronic catarrh of the bladder is distinguished by the discharge of thick, tenacious, grayish muco-purulent matter in the urine, in greater or less abundance, and which gradually subsides to the bottom of the vessel in which it is collected. Under the urine, it appears as a semi-transparent, whitish, tenacious jelly, something like parboiled white-of-egg; and on pouring off the urine, it hangs slightly adherent to the vessel, and then slides down suddenly in a lump; or it can be poured from the vessel in long coils, resembling maccaroni. This mucous deposit may be tinged with blood, or present white streaks of phosphate of lime. The urine itself becomes brownish, ammoniacal and fetid. A typhoid febrile condition accompanies this advanced state of the disease; the

pulse becoming extremely rapid and feeble, the tongue dry and brown, with great prostration and cerebral oppression.

*Causes.*—Acute cystitis may subside into the chronic or persistent form of inflammation. But chronic cystitis may also arise independently from any cause of long-continued irritation of the bladder;—from calculi and other foreign bodies, or tumours in the bladder; or from the retention and decomposition of urine; as in stricture of the urethra, or enlargement of the prostate, or in spinal paralysis. The latter disease is not only a cause of retention, it also induces an inflammatory state of the vesical mucous membrane by impaired nervous supply.

*Treatment.*—The same plan of treatment is appropriate as in acute cystitis, only modified in degree. It comprises derivation from the bladder, correction of an irritant state of the urine, and the influence of opium to allay pain and vesical irritability. But the abundant discharge of mucus or muco-purulent matter and the alkaline state of the urine, which especially characterize chronic *catarrhal* inflammation of the bladder, render certain special treatment necessary; to arrest the secretion from the mucous membrane and to correct the state of the urine. Pareira brava, a concentrated decoction, uva ursi, or the infusion of buchu, given with the mineral acids, are more or less efficacious; I much prefer the concentrated decoction of pareira with diluted nitro-muriatic acid in ten or fifteen minim doses. The acid is more suitable when the urine is itself alkaline, than when it subsequently becomes so by admixture with alkaline mucus in the bladder. Benzoic acid also renders alkaline urine acid, and I have found gallic acid useful in arresting the secretion of ropy mucus. Injections are highly serviceable, when no acute symptoms are present. They may be sedative, as tepid water or decoction of poppies, in quantities of not more than two ounces and retained for half a minute once a day; or astringent injections, as diluted nitric acid, ten minims gradually increased to twenty in two ounces of water. By these measures, coupled with tonics and a generous diet, to support the dread exhaustion of chronic cystitis, we may succeed in arresting the progress of the disease to a fatal issue. In conjunction with this course of treatment, the removal of any cause in operation must obviously be a primary consideration. Hence, the treatment for stone or other foreign body in the bladder, or perchance a tumour in this organ; and the various causes of retention,—stricture, enlarged prostate, or paralysis.

**TUMOURS OF THE BLADDER.**—These diseases comprise:—(1) Fibrous growths, of a warty or of a polypoid character; (2) Villous or vascular growths; (3) Cancer; encephaloid, scirrhus, or colloid.

*Fibrous growth* springs from the mucous membrane and sub-mucous tissue and consists of their elemental structures. It commences in the form of a circumscribed elevation of the mucous membrane, resembling a *warty* growth, and subsequently enlarges, protrudes, and assumes a *polypoid* form.

The *symptoms* are those arising from any cause of pain and irritation, with obstruction to micturition; and there is also the presence of a foreign body in the bladder. Simulating stone, careful sounding to discover the position and form of the growth may show distinctive characters. Phosphatic deposit encrusting the growth may, however, still mislead as to its true nature; but the fixed position, and impossibility of passing a sound around the tumour, free of the bladder, will determine the diagnosis.

This species of growth is most common in children and young persons. The absence of blood in the urine or in any notable quantity, distinguishes warty or polypoid growth from both the remaining species, villous growth and cancer.

The *treatment* is palliative, to allay pain and vesical irritability, with the use of a catheter when necessary. Polypus of the bladder has been removed in two cases; by Civiale with a lithotrite; and by Warner with a ligature, from the bladder of a female after dilating the urethra, the tumour being the size of an egg.

*Villous growth* springs also from the mucous and sub-mucous tissues, and consists of cellular elements and large looped capillaries. It presents in the form of innumerable fine villous processes or tufts, which branch off from the base in every direction. Floating in water, this growth appears as a soft, flocculent body, about the size of a large marble when fully developed. Several such tumours may co-exist, giving to the interior of the bladder a studded villous appearance. The structural identity of the villi with those of the chorion in a healthy state, is remarkable.

The *symptoms* are not peculiar, either with regard to obstruction or the presence of a foreign body in the bladder. But the pain and vesical irritability are much aggravated; and the abundant, foeturecurring draining hæmorrhage, or *bloody urine*, distinguishes this species of growth from polypus. Shreds of the tumour are also apt to appear in the urine, which examined by the microscope, will confirm the diagnosis.

The *treatment* is palliative as for polypus. Astringent injections may perhaps be used, as weak solutions of acetate of lead or nitrate of silver; and astringents taken internally, as gallic acid, may prove serviceable in arresting the tendency to hæmorrhage. Tonics, especially iron and quinine, with a nutritious diet, will be requisite to support the patient under the exhaustion resulting from long-continued pain, irritability of the bladder, and hæmorrhage. The introduction of any instrument must be avoided as much as possible; sounding is less effective in the diagnosis of a growth so soft and flocculent; catheterism aggravates the pain and irritation and may provoke bleeding; while, the removal of villous growth would be equally hazardous and ineffectual.

*Cancer* of the bladder is more common than the last named species of growth. It may be primary, commencing in the bladder; or secondary, extending from the prostate, the rectum, or the uterus. The species is most frequently *encephaloid*, and usually so when originating in the bladder, always of this kind when spreading from the prostate; *scirrhous*, when spreading from the rectum or the uterus, or epithelial cancer from the latter organ. *Colloid* is more rare; but in post-mortem examination, I have met with this species of cancer occupying the whole interior of the bladder, as a semi-transparent, greenish-yellow, trembling, mass of jelly; as if the organ were fully distended with urine. Similar colloid deposits were found in the uterus and rectum, and in most of the abdominal viscera.

*Symptoms*.—The pain of cancer in the bladder is very severe, but scarcely ever lancinating; and is referred to the lower part of the belly, to the loins, hips, thighs, and perineum. Vesical irritability is so active, that the urine is ejected every few minutes; and when ulceration of the mucous membrane ensues, it is expelled with sweating agony. The semen also may be emitted, and the contents of the bowel evacuated, or the bowel itself protruded, during the writhing effort to strain off the

last few drops of urine. Profuse, gushing *hæmorrhage*, or *bloody urine* and of an alkaline, fœtid, purulent character; with perhaps the appearance of cancer-cells in the urine; are tolerably distinctive of cancer-growth in the bladder. But the presence of a solid *tumour* in the situation of this organ at the lower part of the abdomen, is characteristic of cancer; excepting when a non-malignant growth has attained to such size as to occupy the bladder,—a rare event. Then the diagnosis will turn on the general severity of the bladder-symptoms, aided perhaps by the appearance of the cancerous structural elements in the urine. Constitutional symptoms, with glandular enlargements in the iliac regions, may supervene in an advanced stage of the disease; but the peculiar cancerous cachexia is even then not well marked. The patient's general health and aspect is that of a person worn down simply from pain, sleeplessness, and loss of blood.

*Treatment*.—Palliative measures only have any effect; comprising opiates, administered internally and sometimes by injection, tonics, and supporting diet. The disease is invariably fatal.

TUBERCLE of the bladder is a very rare affection; probably never occurring unassociated with tubercular deposit in other parts of the body, and of the urinary system especially; the kidneys and prostate in particular, being similarly affected. In women, it has been known to have followed primary disease in the uterus.

The *symptoms* are not peculiar, and the diagnosis is chiefly negative. Great pain, and extreme irritability of the bladder; with the absence of obstruction to micturition, and of a calculus or other foreign body, of hæmorrhage in any quantity, and of any perceptible tumour; together with the presence of tuberculosis, and progressive emaciation. These circumstances taken in conjunction with the patient's age, usually early or middle adult life, will indicate the nature of this disease.

When the tubercular deposit softens, the mucous membrane gives way, and a large ragged ulcer ensues, before death.

*Treatment* must have reference to the constitutional disease—tuberculosis, and the remedies for chronic cystitis.

HÆMATURIA.—Blood in the urine or simply bloody urine, is a *symptom* only of disease in some part of the urinary organs. Varying in quantity, from a small proportion discoverable only by the microscope, to an amount constituting the greater portion of the fluid passed; the admixture of blood and urine may be recognised by corresponding differences in the colour of the urine. When blood is present in small quantity, the urine has a brownish or smoky tint; and deposits a reddish-brown sediment on standing. In large quantity, the urine has a dark brown, muddy, colour, like chocolate; and deposits a red sediment adhering to the bottom of the vessel. Intermediate tints are met with, according to the admixture of blood. Heat coagulates the blood into a brownish-gray deposit, leaving a clear fluid above; and microscopic examination exhibits the characteristic red blood-discs. These tests, especially the latter, will show the presence of blood in the urine, and thus distinguish hæmaturia from simply dark reddish-coloured urine, due to other causes; bile, rhubarb, and other colouring matters, or to mere concentration of the urinary secretion.

The *source* of the blood in hæmaturia, and thence the seat of the disease, may be any one or more of the following parts; (1) the kidney; (2) the pelvis of the kidney; (3) the ureter; (4) the bladder; (5) the prostate; (6) the urethra.

*Causes.*—Diseases of the kidney, acute and chronic; injury, as blows, strains, etc.; calculus in any part of the urinary tract; violent diuretics, as turpentine or cantharides; cystitis occasionally; prostatic disease; cancer of any part of the urinary organs; villous tumour of the bladder; the hæmorrhagic diathesis; certain blood diseases, as fever, or purpura; stricture of the urethra; chordee; local application of mechanical and chemical agents.

The *diagnosis* of the source of blood in the urine is the same as of these causative conditions. But the general ground of distinction is this:—when hæmaturia is renal, the urine will be uniformly mixed with the blood; when it is vesical or prostatic, the first portion of urine that passes or that is drawn off by the catheter, will be pale and less bloody than the last, and at the termination of the stream, pure blood only may escape.

*Treatment* must always have reference to the cause of hæmaturia,—the disease whence the blood emanates. The general remedial measures are; rest, the recumbent position, and astringents. Gallic acid in particular, sulphuric acid, acetate of lead combined with opium, or Ruspini's styptic, may severally be administered internally; and cold also applied to the hypogastrium, perineum, or within the rectum by injection,—when the hæmorrhage proceeds from the bladder. I am in favour of ice-cold water enemata. The management of the blood collected in the bladder has given rise to a diversity of opinion. It is recommended that the coagulum should be broken up and withdrawn, by the introduction of a full-sized catheter to which a syringe is then applied. This disturbance of the clot would seem to be unnecessary and prejudicial. Its removal may reopen the vessels and renew the hæmorrhage, while the solvent action of the urine will most safely and effectually bring away the blood. Opium may succeed in controlling the urgent desire to micturate; and when absolutely necessary to relieve retention of urine, surgical interference can be resorted to.

**MALFORMATIONS.**—Congenital aberrations of development in regard to the Bladder are fortunately not very common; the misery any such condition entails necessarily precluding the unhappy individual from society. Probably, however, such cases are more numerous than was formerly supposed; as, since surgical attention has been directed to their relief, persons thus afflicted present themselves more frequently at Hospitals and in private practice.

Malformations of the bladder are of three kinds:—(1) absence of the organ, with certain abnormal deviations of the ureters; (a) their direct communication with the urethra, (b) with the rectum, (c) with the vagina; (2) co-existence of two or more bladders; (3) extroversion of the bladder, with corresponding deficiency of the anterior wall of the abdomen, exposing the posterior wall of the organ as a prominent projection.

*Extroversion* of the bladder demands more particular notice, this malformation being susceptible of relief.

With absence of the abdominal wall over the bladder, the pubic symphysis is sometimes absent also. The posterior wall and base of the organ are then pushed forward by the abdominal viscera, and form a prominence; the mucous membrane having a red, vascular appearance, and showing the orifices of the two ureters, whence the urine trickling down, perpetually moistens the surface. From beneath the lower margin, a short imperfect penis depends, which is flattened, as if cleft in the middle line into the urethra. At the root of the penis, a rudimentary prostate

exists, the ducts opening into the angle between the bladder and pubes. A pouch of integument below represents the scrotum, and contains the testes, with usually some hernial protrusion of the bowels beneath the extroverted bladder. Both sexes are liable to this malformation, but it occurs more commonly in the male. In the female, the generative function is not necessarily wanting. But in both sexes, the extroverted mucous membrane is very sensitive and readily bleeds; while the continual distillation of urine, producing excoriation of the parts beneath, and pervading the patient with a constant odour of stale and decomposing urine, renders his life a misery to himself and intolerable to others about him.

*Treatment.*—*Mechanical* contrivances have been made with the view of forming an artificial abdominal wall over the bladder to catch the urine as it flows; thus preventing excoriation and the urinous odour. An india-rubber bag may be fastened over the bladder for this purpose; but great nicety of fit and capability of adjustment to the various positions of the body, are requisite elements in any such contrivance.

*Plastic operations* have also been devised with the view of restoring the deficient abdominal wall, and thus closing in, or as it were, completing the bladder. An ingenious operation of this kind was originally performed by M. Adolphe Richard, in October 1853; it was founded upon one performed by M. Nélaton for a lesser degree of deformity,—simple epispadias, in the early part of 1852. Subsequently, in 1859, Pancoast of Philadelphia, introduced the use of two reversed flaps, taken from the sides of the bladder at the groins, and turned with the skin surface towards the bladder. In the same year, Dr. Daniel Ayres of New York, operated in two cases on the same principle; and the skin at the margin of the exposed bladder was dissected up and brought together by sutures over the raw surface of the reflected flap. Into this country, Mr. Timothy Holmes, was the first to introduce an important modification of the operation,—reversed and superimposed flaps taken from the *groins*, at the sides of the bladder; whereby a better supply of nourishment would be secured, from the recurrent branches of the common femoral artery, and thence the greater probability of union taking place. Mr. John Wood has completed the operation, in all its details, and has been the most successful operator.

The *operation* now consists of two stages; the first, to effect the closure of the upper part of the bladder; the second,—after an interval of about a month, to close in the lower part, and to form a prepuce and complete the urethra. Closure of the bladder is accomplished, by reflecting two triangular flaps of skin, one on each side of the exposed bladder, with their bases downwards, and attached to the skin of the groin at Poupart's ligament. The apex of each flap meets the other at the median line above the extroverted bladder, so that the raw surfaces exposed by lifting them are continuous at that point. The inner edges of the flaps are made close up to the bladder, and are brought together in the median line, and united by interrupted wire sutures. The penis may then be fastened down to the scrotum by a silver-wire suture passed through the frænum, to allow a free escape of the urine. The angles of the groin and umbilical incisions are then to be united by wire sutures. Completion of the urethra and the formation of a prepuce—according to Wood's operation—"consists in raising the whole front of the scrotum, together with the skin covering the lower side of the penis—going deep enough to include the muscular layer of the *dartos*—so that these tissues form a sort of bridge

of skin connected with the groin on both sides. This is then lifted over the penis, which the great extensibility of the parts permits easily to be done, and placed upon a bed or raw surface, prepared for its lodgment by turning down a collar or flap from the arched border of the bladder-covering above, and from the sides of the urethra and penis below, as far forward as the glans. A continuous thin wire suture holds the deeper or reversed flaps together, and a single line of interrupted sutures connects the transplanted scrotal structures to the border of the bladder-covering. The gap in the scrotal wall is afterwards easily closed in over the testicles by the great extensibility of the hinder part of the bag, which is left intact; the margins of the wound being brought together vertically by thickish wire sutures that will not easily cut out."

As to the *difficulties* of these plastic operations, Mr. Wood finds;—that in the first stage—or closure of the bladder, the chief difficulty arises from the hernia-like protrusion of the hinder wall of the exposed bladder by the action of the abdominal walls upon the contained viscera. In the second stage—that of forming the new prepuce and completing the urethra, the chief difficulty arises from the occurrence of erections in the imperfect penis, excited perhaps by irritation of the sutures; thus displacing the united parts, or rupturing the newly-formed adhesions, before sufficiently secure to resist tension.

*After treatment.*—The former difficulty referred to, is best obviated by *position* of the patient, after operation; a sitting posture, with the knees drawn up, tied together, and placed over a high bolster. This relaxes the abdominal and pelvic muscles connected with Poupart's ligament, completely, and also allows the urine to drain off by gravitation from the raw and adhering surfaces. Erections are most effectually controlled by continued *cold applications*, as by irrigation or ice-bags.

*Results of Operation.*—Richard's case was unsuccessful, death ensuing, in nine days, from peritonitis. Ayres' two cases were both successful. Mr. Wood records eight cases of operation (Med.-Chir. Trans., 1869), in none of which was there the slightest approach to peritonitis; and all recovered, except the first case, which terminated fatally, death however not resulting from the operation. The success of operation in curing or relieving the malformation, has been variable; sometimes a perfect result, sometimes a complete failure, sometimes a greatly improved condition.

FUNCTIONAL MORBID CONDITIONS.—The bladder is subject to functional morbid conditions, which may, or may not, involve structural alterations in the organ.

These conditions of function comprise:—(1) irritability of the bladder; (2) spasmodic action; (3) neuralgia; (4) paralysis; (5) atony; (6) frequent micturition; (7) incontinence or involuntary escape of urine; (8) engorgement of the bladder, and overflow of urine; (9) retention of urine.

The anatomical construction of the bladder has important relations to these various functional conditions of this organ. A brief notice of its structure will tend to elucidate their pathology.

The urinary bladder is essentially a hollow expansion of mucous membrane, continuous with that of the ureters above and the urethra below; the function of this membranous bag being simply to receive and retain the urine, as secreted by the kidneys and conveyed by the ureters; until convenience may permit of its discharge through the urethral passage of exit, from time to time. Accordingly, the external aspect of this receptacle is closely surrounded with bands of muscular fibres—the un-

striped variety—disposed, amid cellular tissues, in figure-of-8 spiral loops, running vertically, obliquely, and horizontally.\* These muscular bands are plentifully supplied with blood-vessels—the superior and inferior vesical arteries—with also some branches of the uterine arteries in the female—both of which are divisions of the internal iliac artery; they inosculate and issue in large plexuses of veins. The latter are situated chiefly at the neck, sides, and base of the bladder, and terminate in the internal iliac veins. Lymphatics accompany the veins in their course. Nerves are supplied, partly from the sacral plexus, itself derived from the spinal cord, and these nerves are also distributed on the base and neck of the bladder; but a large supply coming from the hypogastric plexus of the great sympathetic is distributed on the upper surface and remaining portion of the bladder, not supplied by the sacral plexus of nerves. The muscular bands, blood-vessels, lymphatics, nerves, and cellular tissue, together form a second layer or coat, superimposed on the “mucous coat,” in which the vessels and nerves ramify and terminate; while externally, this “muscular coat” is partially invested by a reflexion of the peritoneum, forming the “peritoneal coat.”

**IRRITABILITY OF THE BLADDER.**—This functional condition is denoted by *frequent micturition*, of a more or less painfully urgent character.

The healthy irritability or contractility of the bladder is the vital property of the *muscular bands*, in its middle coat. Stimulated by the urine accumulated in the bladder, they contract both vertically and transversely; and by their combined action—aided by the voluntary action of the abdominal muscular parietes compressing the viscera downwards on the bladder—the contents of the organ are expelled, as occasion may require. The pathological condition of undue or increased irritability is, therefore, immediately referable to the muscular or middle coat of the bladder; but the painfully urgent desire to evacuate its contents, results from a similar exalted sensibility of one or other systems of *nerves*, or may be referable to both.

Irritability of the bladder—thus a musculo-nervous functional condition of this organ—is itself a symptom only; yet it is one which has a wide-spread etiology, comprising both local and constitutional causes; the latter relating chiefly to morbid states of the blood, or of the nervous system, and connected frequently with various hygienic and social habits of life. Vesical irritability is, therefore, not merely a symptom which may be selected for the convenience of associating much valuable clinical experience pertaining to diseases, different in themselves. As a symptom, it may have also a valuable *etiological* significance, by leading to the discovery of latent disease in operation, in perchance some distant and previously unsuspected organ or part of the body; while the continued operation of any such disease, and thence its *prognosis*, may perhaps be determined by the persistence of the vesical irritability. Consequently, rational curative *treatment* can be brought to bear upon the disease, which has been thus indicated and estimated.

**Causes.**—The bladder has its nervous and vascular relations to surrounding organs, and to organs distant in the body—both in health and disease. This two-fold relation to other organs, through the medium of the nervous and vascular systems, is the key to the etiology of irritability

\* Original Dissections by J. B. Pettigrew. Museum Roy. Coll. of Surgeons; and, same authority, “On the Muscular Arrangements of the Bladder and Urethra,” &c. Phil. Trans., 1867.

of the bladder. But, the organ itself may be the seat of irritation, in disease of the bladder; or its contents may be the source of direct irritation, as by the presence of stone, blood, or morbid conditions of urine.

All the causative conditions of vesical irritability are conveniently arranged under two general heads:—

*Local causes.*—Diseases of surrounding organs which cluster around the bladder, may severally operate as causes of its irritability. The majority of these diseases affect the bladder through either its nervous or vascular relations with the organ diseased. But, some apparently act *mechanically*, in reducing the *capacity* of the bladder as a receptacle for urine; by pressure from a tumour of the rectum or uterus, or by displacement of the latter organ. Diseases of the bladder itself may sometimes act mechanically in like manner; by hypertrophy or thickening of the wall of this organ, or by chronic enlargement of the prostate. In either way, the capacity of the bladder being diminished, while the quantity of urine secreted and conveyed into it continues undiminished, or is perchance increased; a more frequent discharge of urine is necessitated—a more frequent micturition, and thus the phenomenon of vesical irritability will be established. Other organic diseases of the bladder, as cancer, may operate in part mechanically; but more especially, by inducing an exalted state of the *vital* property of *irritability* or contractility in the muscular coat of the bladder. Cystitis, in the acute stage of inflammation, being unattended by any notable thickening of the bladder, would seem to have a similar influence. So also morbid contents of the bladder; as various conditions of the urine, the presence of blood or of a stone.

The various local diseases which operate as causes of vesical irritability may be enumerated in connexion with the organs themselves, as follow:—(1) Habitual constipation and Diseases of the Rectum; principally—hæmorrhoids, fissured anus, inflammation of the rectum, stricture, cancer, abscess about the rectum, and fistula in ano; (2) Displacements and Diseases of the Uterus and Vagina; chiefly—prolapsus uteri, or vaginæ, acute inflammation of the uterus, cancer, fibrous tumour; (3) Stricture of the Urethra, organic, spasmodic, inflammatory; (4) Diseases of the Prostate gland; chiefly—chronic enlargement, inflammation, cancer, and other tumours; (5) Diseases of the Bladder; chiefly—hypertrophy, cystitis—acute and chronic, cancer, stone, hæmorrhage. Morbid conditions of the Urine, with Urinary Deposits, rank as local causes of irritability by their direct operation on the interior of the bladder; but as pertaining to Urinary Pathology, they are included under the second general heading.

*Constitutional causes.*—This great class of causes embraces, (1) morbid conditions of the blood, (2) those of the nervous system.

Morbid conditions of the *Blood* result from perversions of the blood-forming processes; (*a*) by mal-assimilation, primarily in the process of digestion, or secondarily in that of nutrition; (*b*) by mal-excretion, through the kidneys, skin, or liver. Diseases of the *organs*, severally concerned in these processes, give rise to the consequent blood-conditions; and they, in their turn, are manifested by corresponding states of the urine and urinary deposits; the whole constituting Urinary Pathology. In relation to irritability of the bladder; the organic conditions are remote causes, the urinary conditions are direct or immediate causes; while the blood-vascular system is the medium of communication. The chief

of the causative urinary conditions are; lithic acid and lithates; oxalates; and phosphates.

Morbid conditions of the *Nervous System* comprise diseases of the Nervous centres—brain, and spinal cord; and of the ganglionic centres of the sympathetic nervous system. Diseases of these central *organs*, and of organs generally, being severally connected through the nervous system, they may thence become causes of vesical irritability.

It thus appears that diseases of organs *distant* from the urinary bladder in the body, are brought to bear upon this organ, through the agency of the nervous and vascular systems; just as *local* diseases generally operate, in like manner, upon it. Hence, the wide-spread etiology of irritability of the bladder.

*Treatment*.—Remedial measures must of course have reference to any cause or causes in operation. The treatment of local causes will be found in the various sections of this work, as pertaining to Diseases of the Rectum, &c. But the treatment of constitutional causes, both from a remedial and preventive point of view, is a large and special subject, which is more fully considered under Urinary Pathology in my treatise on the Irritable Bladder, than would be possible within the limits of a general work on Surgery.

**SPASM OF THE BLADDER.**—This affection is said to be an involuntary, uncontrollable, and exceedingly painful contraction of the bladder, occurring from time to time; the cause usually being inflammation, stone, morbid growths, &c. Spasm, like irritability, is a symptom only, of which disease is the cause. I am disposed to regard both these symptoms as the same, but as differing in their degree of intensity; spasm representing excessive irritability, and an acutely painful urgency of micturition.

The *treatment* of this affection is that of cystitis, and the removal of any foreign body from the bladder.

**NEURALGIA.**—Excessive sensibility of the neck of the bladder is an occasional affection; unaccompanied with any apparent disease discoverable during life or after death. A correct diagnosis is very important; lest perchance stone in the bladder, or some disease of the organ be mistaken for neuralgia; or the worse error be committed, of attributing a merely neuralgic affection to some such organic cause.

*Treatment* must be conducted on ordinary principles; anodynes general, and topical by suppositories, with tonics, a well-regulated diet and state of the bowels, change of air, and other hygienic resources.

**PARALYSIS OF THE BLADDER.**—This condition of the bladder signifies a loss or impairment of the contractile power of its muscular fibres, by failure of the nervous supply to this organ.

The paralysis may be partial or complete, and the usual cause is some lesion of the cerebral or spinal nervous centres. Thus, it occurs in connexion with injury to the brain or spine; or from disease, as apoplexy, softening, or other structurally destructive disease. Sometimes, the paralysis seems to be dependent on functional conditions; as spinal debility induced by sexual excesses; reflex action from some adjacent source of irritation, as hæmorrhoids and after operations for their removal; the shock of injury; the result of fever; and the influence of certain medicinal agents, as belladonna, hyoscyamus.

These two classes of causative conditions have each an important characteristic. The *functional* causes of paralysis of the bladder have only a temporary effect; and the *structural* causes generally involve other

parts—they are not restricted in their action to local paralysis of the bladder alone. Such limited paralysis of the whole organ, producing retention of urine, or of its neck only, producing incontinence, is extremely rare; it is usually not a paralytic condition, but simply atony from over-distension.

*Treatment.*—Palliative measures consist in emptying the bladder from time to time, and in the treatment of chronic cystitis consequent on the paralysis and retention of urine. The urine must be drawn off, two or three times a day, by means of a full-sized catheter. It should be used gently, the bladder having lost its sensibility to pain when injury is inflicted, and the urethra being often in a lax state. Chronic cystitis should be treated principally by local means; injections of tepid water to wash out the bladder, followed by weak astringent injection. Curative measures must be directed to the restoration of innervation—the supply of nervous influence.

In chronic cases, not traumatic; strychnia, iron, arsenic, cantharides, and ergot of rye, may prove beneficial; while, of local agents; blistering, cold douches, and electricity, are the most promising.

ATONY, FROM OVER-DISTENSION.—It is highly important to observe the distinction between this condition of the bladder and paralysis. Unlike the latter condition, atony always arises from some organic obstruction—stricture or enlarged prostate, mechanically impeding the evacuation of urine, or from long-continued retention; thus overcoming the contractile power of the bladder, instead of arising from any failure of this power. The resistance offered to the passage of urine, or by its accumulation, is simply greater than the expelling force. Hence, a portion remains behind after each act of micturition, and this residual urine having amounted to twenty or even thirty ounces in quantity, it begins to expand the neck of the bladder; leakage takes place, when strong expulsive force is exercised or by relaxation of the sphincter during sleep. But the resistance prevails, and the contractile power is gradually more and more overcome by continued distension of the bladder; until the muscular fibres are over-stretched, and the cavity of the organ becomes proportionately enlarged. The bladder is in a permanently atonic, and enlarged condition.

*Treatment.*—Curative measures will consist in the removal of any cause of obstruction to the free passage of urine, and the prevention of its accumulation in the bladder. The urine should be regularly drawn off once or twice a day, in order to enable the muscular fibres to recover their normal condition of contraction and tone. By this mechanical relief, a more or less completely successful result may be produced. At the same time, the tone may then be reinforced by medical treatment; chiefly, by the stimulants of nervous action, general and local, employed in paralysis. Injections of cold water into the bladder, have a direct and marked beneficial effect.

Certain *modifications* of the function of *micturition* remain to be noticed.

FREQUENT MICTURITION—whether of an irritable or spasmodic character. This modification of micturition has been already noticed. I introduce it here merely as a standard of contrast with the following modifications of this function.

INCONTINENCE OF URINE.—An involuntary escape of urine differs from frequent micturition, which is of a voluntary, although painfully urgent character.

Incontinence may occur under two opposite conditions. In *children*, and only during sleep, when the voluntary power of retention is temporarily suspended, the bladder then emptying itself; in *adults* of all ages, from retention amounting to *over-distension*, a certain quantity of the urine then running off and leaving a quantity still retained, an event which may happen during sleeping or waking. An involuntary escape of urine in the adult, always indicates a *distended*, not an empty state of the bladder.

The *causes* of incontinence differ accordingly. In childhood, it generally arises from debility, or intestinal irritation; in adult life, its causes are those of retention—paralysis affecting the bladder, atony from over-distension, stricture, enlarged prostate, cystitis, stone. In the *female*, incontinence is generally the result of some injury to the urethra, impairing or destroying the action of the sphincter; such as sloughing from pressure in difficult labour, from the application of instruments in delivery, or from over-dilatation of the urethra for the removal of stone in the bladder.

The neck of the bladder may be the seat of *structural* disease, or malformation. The incontinence is then usually a *continual* dribbling, the urine running off from the bladder as fast as it arrives there from the kidneys. This condition, therefore, differs from both the ordinary modes of incontinence, in childhood or adult life. It differs also from frequent micturition; not only in its involuntary character, but in there being no distinct acts of micturition.

*Treatment.*—In *children*.—A general tonic plan of treatment is indicated, combined sometimes with sedatives. The vinum ferri is especially beneficial; and Sir H. Thompson speaks highly of the extract of belladonna; commencing, according to the age of patient, with the sixteenth to the eighth of a grain twice a day, and increasing the dose as far as it can be safely borne, when requisite. In extremely obstinate cases, he has succeeded by applying a solution of nitrate of silver, ten grains to the ounce, to the prostatic portions of the urethra and neck of the bladder. And in the female, this remedy is also easily applicable. Any source of intestinal irritation, as worms, must be removed. Under this course of treatment, the child, who previously had wetted his bed perhaps every night, may at length retain his water; care being taken not to allow the whole night to pass without seeing that the little patient's bladder is relieved voluntarily. With proper management, the child will, after puberty, generally outgrow the complaint.

In *adults*,—Catheterism, to relieve the distended bladder, is always the primary indication of treatment. Other remedial measures must have reference specially to the causes of incontinence.

ENGORGEMENT OF THE BLADDER, AND OVERFLOW OF URINE.—The *regorgement* of the bladder, of French authors, consists in partial retention of urine, and occasional *overflow*, of quite an involuntary character. It depends on the mechanical obstruction of enlarged prostate; this body rising up at the neck of the bladder and forming a corresponding receptacle behind it, in which urine accumulates. When the fluid rises above the level of the enlarged prostate, an overflow takes place, leaving the bladder still engorged. This state of repletion and overflow is proportionate to the size and obstruction offered by the prostate.

The *treatment* by catheterism, as peculiar to enlarged prostate, will be described with that condition.

RETENTION OF URINE.—This *absence* of micturition is considered in connexion with Stricture of the Urethra.

## CHAPTER LIX.

## DISEASES OF THE PROSTATE.

THE Prostate Gland, surrounding the neck of the bladder and commencement of the urethra, is subject to certain Diseases; Inflammation or Prostatitis, acute and chronic; Hypertrophy or simple enlargement, in advanced age; Atrophy; Cancer; Cysts; Tubercle; Calculus.

These diseases, identical in their nature with the same diseases of other parts, require notice only in so far as they present symptoms peculiar to the prostate, and relative to the bladder; which accordingly modify the treatment.

INFLAMMATION OF THE PROSTATE, OR PROSTATITIS.—*Acute* prostatitis rarely occurs unconnected with inflammation of the bladder or of the urethra.

*Symptoms.*—A sensation of weight and fulness about the neck of the bladder, rectum and perineum; frequent and painful micturition, the pain increasing towards the close of the act, and great pain in defæcation; an enlarged, and exquisitely tender state of the prostate is discovered by examination with the finger introduced into the rectum. The accompanying inflammatory fever is often very acute; commencing with rigors, and leading to a high degree of constitutional disturbance.

As the prostate enlarges, micturition becomes difficult, and total retention may ensue from the obstruction. An attempt to pass an ordinary catheter, encounters opposition, and produces great pain, when the instrument reaches the neck of the bladder.

*Causes.*—Prostatitis is usually a consequence of gonorrhœa, the urethral inflammation extending upwards to the prostate; or of injury by the violent use of stricture or lithotripsy-instruments; or it results from the irritation of a calculus, strong injections, or cauterization of the prostatic urethra. Cold and damp to the perineum, will also give rise to it, and especially in gouty or rheumatic subjects. Occasional causes are; alcoholic drinks, and inordinate sexual excitement; when, in either case, urethritis already exists. As an idiopathic inflammation it is very rare.

It terminates in the course of a few days, in resolution, or in suppuration, or becomes *chronic* inflammation.

*Treatment.*—Local blood-letting from the perineum, affords the greatest relief. Ten or twenty leeches should be applied, or cupping performed to the amount of six or eight ounces; followed by warm poppy-head fomentations and hip-baths. A free purgation, and subsequently gentle action of the bowels; with antimonial salines, and low diet; constitute the remainder of the treatment. Retention of urine may yield under a full dose of opium, or necessitate the occasional use of the gum-elastic catheter. By promptly adopting these measures, the inflammation may subside, without suppuration; although there is always a liability to relapse, the prostate remaining enlarged and hardened for some time; and there is some difficulty or delay in the passage of the stream of urine.

*Abscess of Prostate.*—Suppuration is preceded by throbbing about the neck of the bladder or in the perineum; the rectal swelling becomes softer, and fluctuation may be perceptible; pus appears in the urine,

when the abscess bursts into the urethra and discharges through that passage. Generally, the urethral opening soon closes; if it remains open it becomes a receptacle for urine, and induces abscess in the perineum. Sometimes, the abscess opens through the rectum, and may result in the establishment of urethro-rectal fistula. Not unfrequently, the abscess is burst by the introduction of a catheter, in relieving the retention of urine caused by the enlarged gland; the matter being drawn off through the instrument. The quantity discharged may be considerable.

*Peri-prostatic abscess* occurs in not a few cases; the matter forming external to the prostate, and not within the capsule of the organ. Such abscess is of less serious import than prostatic abscess.

*Treatment* should be prompt and decided with the view of giving vent to any formation of matter. When, therefore, there is a tendency to perineal pointing, as indicated by brawny induration, without any fluctuation; an incision should at once be made in the middle line, about three-quarters of an inch anterior to the anus, and down to the matter; taking care to avoid the rectum. With this view, the fore-finger of the left hand should be introduced into the bowel; a long, straight, and narrow, sharp-pointed bistoury used, and the edge be directed upwards. The depth to which the incision must be carried will be an inch and a half to two inches, and it is extended straight upwards in the raphé just sufficiently to give a fair patulous aperture. Relief is immediate. If no pus makes its appearance, the relief of tension and pain will be effected, and the matter may escape through the wound after poulticing for a few hours. Thus then, communication with the urethra or rectum is prevented. Puncture through the rectum has been made occasionally, when fluctuation was distinctly felt in that situation.

Peri-prostatic abscess must be treated in like manner, there being no practical distinction between it and prostatic abscess.

*Chronic inflammation* results in enlargement of the prostate; with frequent micturition, but a less forcible propulsion of urine, followed perhaps by a drop or two of blood; usually also there is a gleet discharge, and the urine is milky and deposits more or less pus on standing. Pain in sexual intercourse, and nocturnal emissions are often experienced. These symptoms are much increased by riding on horseback or prolonged walking exercise, and by errors of diet. Examination with the finger per rectum will discover the prostatic enlargement.

*Treatment* consists in counter-irritation to the perineum, and careful regulation of the digestive organs; the administration of iodide of potassium, tonics, especially iron and quinine, and a supporting diet. Nocturnal emissions are best overcome by the application of nitrate of silver to the prostatic urethra. By pursuing this course of treatment for a long period, a cure will generally be effected.

**CHRONIC ENLARGEMENT, OR HYPERTROPHY, OF THE PROSTATE.**—This prostatic affection is of common occurrence after the age of fifty-five to sixty years; but it never happens before the first named period, and extreme old age seems to be less liable to it. Age and this prostatic enlargement are, therefore, invariably associated. Chronic inflammatory enlargement of the prostate may occur at any age after puberty; but the chronic enlargement of the gland in advanced life is quite distinct from any inflammatory state, it is an hypertrophied condition.

*Structural condition.*—The dissections by Sir H. Thompson and by Dr. Messer, have thrown much light on the structural alterations which

constitute chronic enlargement of the prostate. The tissues of which the prostate gland consists—in its normal or anatomical structure—are; first, unstriped muscular fibre, with connective tissue; forming at least three-fourths of the prostatic body; secondly, interspersed among this structure are numerous branching glandular tubes and cysts with their accompanying ducts. Enlargement or hypertrophy may be determined by an abnormal production of the first-named elements alone; or with some of the glandular tissue interspersed, and which may be imperfectly or fully developed. The *parts* of the prostate thus affected; may be the two lateral lobes, which are sometimes increased to four or six times their natural weight and bulk; or an outgrowth may take place from the central part of the organ, in a backward direction towards the cavity of the bladder, as a more or less rounded or pyriform tumour of prostatic tissue,—the enlarged “middle or third lobe;” and this form is one most commonly met with. Generally, the whole organ more or less partakes in the enlargement. *Isolated* tumours of prostatic tissue are also very commonly produced, and found imbedded within the proper structure of the prostate. Consisting principally of the unstriped muscular tissue, they form small rounded bodies, sometimes completely isolated by a limiting fibrous cyst. These small imbedded tumours seem to have a relation to the containing organ, similar to fibrous tumours in the uterus.

*Signs.*—The *physical* characters of the enlarged prostate are not so definite as the structural condition. In consistence, it is usually firmer and harder than natural, as if the organ were enclosed within a tight or stretched envelope; sometimes, it feels looser and softer than natural. The formation of numerous fibrous tumours within the prostatic substance, will more especially present the former character. In external colour there is no change from the healthy state, unlike malignant enlargement. The weight and size of a simply enlarged prostate are sometimes very remarkable. Taking the average weight of a healthy prostate to be  $4\frac{3}{4}$  drachms; the average size is,—from base to apex  $1\frac{1}{4}$  to  $1\frac{1}{2}$  inch, transversely  $1\frac{3}{4}$  inch, exceeding the antero-posterior diameter by a fourth or fifth; and the greatest thickness,  $\frac{5}{8}$  to  $\frac{7}{8}$  inch. (H. Thompson.) Weight is a fair index to size. The enlarged prostate reaches commonly to 8 or 12 drachms, or more than double the natural size. A prostate weighing an ounce, will have attained to the size of one inch in thickness from before backwards, and two inches in a transverse direction. Three inches transversely is not uncommon, and even four inches or rather more has been attained. The weight has been known to reach to twelve ounces.

*Structural alterations in the Prostatic Urethra, and Neck of the Bladder.*—The consequence of prostatic enlargement is obstruction to the passage of urine; and this produces certain structural changes in the vesico-urethral portion of the canal. The *prostatic urethra* undergoes enlargement in its antero-posterior diameter, with diminution of its transverse or lateral diameter, the canal becoming a narrow passage; instead of being, when distended, of nearly equal diameter in both directions. In point of length this portion of the urethra is also much increased; measuring perhaps four inches from the orifice of the bladder to the membranous portion; instead of its normal length, one inch and a half. Its direction deviates also; with enlargement of the middle lobe, the urethra rises abruptly as an angular curvature instead of a nearly straight line; thus presenting a complete step or “bar at the neck of the

bladder," over which an instrument must be made to pass before it will enter the cavity. An outgrowth from the middle lobe occasionally forms as a valve, overlapping the vesical orifice; and which being forced forwards in the act of micturition, more completely obstructs the passage of urine. With enlargement of either lateral lobe, in addition to that of the middle portion, the lateral direction of the prostatic urethra is also changed; curving to the left, when the right lobe is enlarged, and *vice versâ*. The *vesico-urethral orifice* or opening of the bladder, undergoes alterations of shape; becoming crescentic, with the convexity turned upwards, when the middle lobe is enlarged; or turned to the left or right, according as the enlargement of the lobe on the *opposite* side predominates.

Thus then, the urethral canal, as a whole, is always *elongated* and *more curved*; while the prostatic portion and vesical orifice may sometimes together have a *tortuous* course. These alterations, however, are necessarily alike dependent on the prostatic portion of the urethra; or as regards the vesical orifice, on the prostate just within the bladder.

The *causes* of chronic prostatic enlargement or hypertrophy, are obscure. Various causes have been assigned, all of which are disproved by the searching examination to which Sir H. Thompson has submitted this question. All circumstances which tend to induce active determination of blood to the part, may aid in the development of hypertrophy. Hence, emotional excitement of a sexual kind, actual excesses, overstimulating food, sedentary habits, horse-exercise, and such like, may be enumerated as accessory causes of this affection. But the *initial* cause or origin seems to be unknown.

*Symptoms.*—Commencing insidiously, chronic enlargement of the prostate makes some perhaps considerable progress before any marked symptom supervenes. Then, the symptoms manifested are:—increased frequency of micturition with more or less urgency of desire; a bearing-down sense of weight about the neck of the bladder and rectum, with perhaps pain in the glans penis and testicles; a less forcible propulsion of urine with delay rather than difficulty in its passage, but each act of micturition is felt to be incomplete and is concluded by an involuntary leaky dribbling; there may be slight hæmorrhage occasionally, and some muco-purulent discharge from the urethra. In addition to these four groups of symptoms, which severally may arise from other causes than enlargement of the prostate; there is the physical sign of an enlarged, and more or less hardened, state of this body, as discovered by introducing the fore-finger into the rectum, and feeling in the situation of the prostate at the neck of the bladder.

Taking these symptoms in order, each may be observed more particularly. Increased frequency of micturition occurs mostly after the bladder has become distended during sleep, on rising in the morning, when the desire for relief returns in a few minutes. Uneasiness about the neck of the bladder may induce such expulsive efforts as to strain away some of the contents of the bowel during the act of micturition, at length leading to prolapsus and hæmorrhoids. Flattened motions and frequent erections of the penis, are also not unfrequently concomitant symptoms. Increased frequency of micturition alone might seem to denote that the bladder cannot retain urine, owing simply to irritability of the organ; but the diminished force with which the stream is propelled, with the delay before it is established, and the sense of incomplete relief after apparently

completing the act, are very significant of the state of the bladder. It cannot evacuate the urine, and remains, partially at least, distended.

Pathology supplies the true explanation of all these symptoms. The enlarged prostate projects upwards into the bladder, and urine accumulates in the receptacle thus formed behind the prostate. The bladder is never emptied below the level of the prostatic projection. Consequently, frequent, straining, efforts are made; but the stream issues with less propulsive force, slowly, and ineffectually; the surplus urine only or overflow passing off, the residual urine, often in large quantity, still remains below the prostate in the bladder. Even this occasional discharge can occur only when the bladder is sufficiently distended to obey its own contraction, and the straining compression of the abdominal muscles, to overcome the resistance offered by the enlarged prostate. An involuntary dribbling of urine takes place occasionally, from over-distension; the incontinence of adults. Attacks of complete retention may supervene from any cause of temporary prostate congestion; as by exposure to cold or damp, sexual excitement, or some error in diet; and such an attack is sometimes the first occasion of discovering the existence of prostatic enlargement. Complete retention, and a distended state of the bladder, is indicated by dullness on percussion above the pubes, extending possibly as high as the umbilicus. The slight hæmorrhage, and perhaps mucopurulent urethral discharge, not unfrequently happen under similar circumstances of prostatic congestion. Profuse hæmorrhage has been known to occur from transfixing a projecting portion of the prostate, in incautiously or forcibly passing a catheter.

The enlarged prostate as *felt* on introducing the finger into the rectum, varies in size and consistence. Usually it is that of a large chestnut, or a small compressed orange, and of largest extent transversely, —stretching perhaps across the upper surface of the bowel from side to side at the neck of the bladder; or either lateral lobe may be enlarged singly, the right or the left. The consistence is usually firm and resisting, sometimes soft or unequally hard at different parts of the surface. It may be impossible to ascertain the extent of the enlargement backwards, which is often beyond reach of the finger. By tilting upwards and forwards the base of the bladder, some of the residual urine may be expelled; or by passing a catheter through the urethra, several ounces of urine, ten, twenty, thirty, forty, or more, may be drawn off, although the act of micturition had just previously been performed. The patient who had imagined his inability to retain, is now convinced of his inability to expel his urine,—that his bladder retains too much.

*Urethral exploration* with a catheter will afford information which rectal exploration cannot convey, respecting the state of the middle lobe, and as to the elongation and curve of the urethra in its prostatic portion; thus completing the examination. For this purpose it is better to use first, a full-sized catheter of the ordinary length and curve, as the standard of comparison; so that any alterations from the healthy condition may be at once made apparent. If, with no perceptible enlargement by rectal exploration, the urine flows when the instrument has traversed not more than the ordinary distance,—about six to eight inches; while the handle has not been more than usually depressed; there will assuredly be no prostatic enlargement. But, if the catheter has passed easily nine or ten inches and still no urine flows; while following its course, the handle has become more than usually depressed; there will assuredly be prostatic

enlargement. Then the *prostatic catheter* should be used; a longer instrument by from two to four inches, and having a much larger curve.

FIG. 452.

(Fig. 452.) The increased length and the direction of the prostatic canal can be estimated by means of this instrument; the one fact, by observing the length of shaft introduced; the other, by its position when the point enters the bladder. Any deflection of the instrument, to the right or to the left, when allowed to take its own inclination, will further indicate a greater degree of enlarge-

ment on the side *towards* which the handle inclines.

Examination of the prostate, thus far, may be conducted advantageously, by using the finger in the rectum and the catheter in the bladder, at the same time; the concerted movements of the two instruments indicating, moreover, the thickness of the prostate, as well as the length and course of the prostatic urethra.

Exploration of the urethro-vesical orifice and of the vesical portion of the prostate, with the fossa or receptacle behind it; can be severally effected by means of a *sound* having a very short curve or only a beak. On passing this instrument into the bladder the beak is then turned down, and the post-prostatic receptacle sounded as to its depth, and searched for stone,—a not uncommon concomitant of enlarged prostate; in withdrawing the beak forwards, the posterior limit of the prostatic enlargement is ascertained,—a point not often ascertainable by rectal exploration; then the state of the middle lobe is determined, more clearly than by the upward curve in entering the bladder; finally, the condition of the vesical orifice, by turning the beak round to the right and to the left.

*Diagnosis.*—Enlargement of the prostate must be distinguished from; (1) stricture of the urethra, (2) stone in the bladder; (3) tumour of the bladder; (4) simple atony of the bladder; (5) paralysis.

In *Stricture*, the diminished force of the stream of urine is the same, or even less; but the volume is also diminished, even to that of the smallest stream short of retention; and, moreover, it becomes variously broken, twisted, or dribbling. Catheterism affords, however, the chief points of distinction; obstruction is encountered always before the instrument reaches the prostatic urethra, and generally before six inches of the instrument have disappeared. In enlarged prostate, seven, eight or nine inches of the instrument will have disappeared without encountering obstruction; and not necessarily then, if the instrument be of sufficient length to enter the bladder. But the handle must be depressed between the patient's legs to a much greater degree than in passing stricture. The difference of age in the two cases will corroborate the diagnosis; stricture almost invariably appearing before middle life; prostatic enlargement not until after that period.

*Stone* in the bladder may be distinguished from enlargement of the pro-

state by certain features pertaining to each of the symptoms. Pain in the glans penis and vesical irritability are most marked *after* micturition, when the bladder is empty and the stone settles down on the more sensitive base of the bladder behind the prostate; and these symptoms are also then aggravated by exercise or any movement whereby the stone rolls about on that part. The stream of urine often stops suddenly, by the stone falling over the vesical orifice; but this symptom is liable to happen also when an outgrowth from the middle lobe of the prostate exists in the form of a valve,—which from time to time overlaps the neck of the bladder, a rare form of prostatic enlargement. Vesical hæmorrhage is of more common occurrence as a symptom of calculus; the blood passed, florid and unmixed, is more abundant in quantity, and it is especially liable to occur *after* exercise by attrition of the stone on the mucous membrane of the bladder. Sounding affords conclusive evidence of stone, when the foreign body can be distinctly struck.

The *co-existence* of stone with an enlarged prostate,—a not unfrequent combination, renders the diagnosis far more ambiguous. If the calculus lies in the receptacle behind the enlarged prostate, the pain in the penis and vesical irritability will be less marked or *absent*; owing to the removal of the foreign body from the sensitive neck of the bladder. Any indication by the sudden cessation of the stream of urine, being equivocal evidence; it is then that occasional hæmorrhage, and especially careful sounding, as already described, afford the most reliable ground of diagnosis as to the existence of stone. Rectal exploration will more completely discover the prostatic enlargement.

From *non-prostatic tumour*, chronic enlargement of the prostate may be known principally by careful urethral exploration, with the beaked sound; and by examination of any urethral discharge with the microscope, which reveals perhaps the presence of characteristic structural elements.

From simple *atony* of the bladder, the diagnosis of enlarged prostate turns upon the twofold fact; that when a catheter is introduced into the bladder, no urine or scarcely any flows;—in the recumbent position, nor is it much propelled by any efforts of the patient. Atony may, however, have supervened from over-distension, as a consequence of prostatic enlargement. In *paralysis* of the bladder, when a catheter is introduced, urine flows, and in a stream as full and forcible as after removal of the obstruction of an enlarged prostate; but there is inability on the part of the patient to propel the urine by any voluntary action of the abdominal muscles,—this inability being of course proportionate to the completeness of the paralysis. The lower extremities also are almost always involved, and this paralytic condition results from injury or disease of the nervous centres,—brain or spinal cord.

*Consequences, and Terminations.*—*Chronic* cystitis, or a state of the bladder bordering on it, commonly ensues from the habitual retention of urine and distension of the bladder. Hence, the characters of the *urine* in chronic enlargement of the prostate, are such as depend on decomposition of some of its constituents, from retention, mixed with the products of chronic inflammation of the vesical mucous membrane. The interior of the bladder changes in colour to a grayish-slate hue, as seen after death; and viscid mucus or purulent matter, streaked with whitish phosphatic deposit, and occasionally tinged with blood, is voided in the urine; which is now alkaline, and of a pungent ammoniacal or fœtid odour. The quantity

of urine passed varies much from day to day; the measure being generally much above, although sometimes below, the average healthy standard. The patient's general health declines during the course of his habitual retention, and inflammatory affection of the bladder. As the result of broken rest, from ineffectually relieving the bladder, and constitutional disturbance owing to the state of the organ; he becomes sallow and dejected, he loses flesh and strength, and "ages" fast. Occasional attacks of complete retention throw him further back. A *gradual decline* of health takes place; or *rapid depression* may occur; from ulceration or sloughing of the bladder, with repeated hæmorrhage, or from profuse purulent discharge. *Uræmia*, from suppression of urine sometimes closes the scene.

*Post-mortem Examination.*—Certain *pathological conditions* of the bladder, ureters and kidneys, result from the mechanical and backward effect of long-continued retention of urine. They are discovered *after* death. The *bladder* is thickened, principally in its muscular coat, and its hypertrophied muscular bands project inwards in the form of prominent fasciculi; between which the mucous membrane protrudes externally and has become sacculated, under the constant pressure of the retained urine. At the base of the bladder, a pouch or receptacle has formed behind the enlarged prostate, capable of holding perhaps several ounces of the ammoniacal, fætid, urine; and in which mucous and phosphatic concretion-matter, are also apt to accumulate. The backward pressure of urine distends, and eventually dilates the *ureters*; and the secreting substance of the *kidneys*,—in their pyramidal and cortical portions, are atrophied; resulting perhaps in sacculated remnant kidneys. Hence, necessarily, suppression of urine, and uræmic blood-poisoning.

*Treatment.*—Palliative measures alone have any effect in chronic enlargement of the prostate; and they relate to the relief of retention by catheterism or other operative interference; and the prevention or relief of chronic cystitis, and the maintenance of the general health.

*Retention of Urine.*—Having regard to the constant retention of a certain quantity of residual urine in the bladder; the organ should be emptied mechanically, at least once a day, or twice or three times; according to the amount of obstruction and the consequent accumulation of residual urine. The *prostatic catheter*, is larger-sized, longer, and more curved than an ordinary catheter; and thus being adapted to the corresponding alterations in the urethra, the urine can be more conveniently drawn off by this instrument. Two points should be observed in passing the instrument into the bladder; not to mistake the dilatation of the prostatic urethra for the bladder, an ounce of urine perhaps thence escaping as if the instrument had entered its cavity; and in the next place, to depress the handle of the instrument sufficiently to curve upwards into the bladder and avoid hitching against any enlargement of the middle lobe. Care should be taken to empty the receptacle behind the prostate, by turning and depressing the point of the instrument. The patient should be taught to pass it in his own person; that he may relieve himself as occasion requires. As a rule, it will be unnecessary and undesirable to allow the catheter to remain in the bladder; but if it be requisite to procure ease and sleep, this continued use of the instrument will be highly beneficial. It may be left in the bladder during the night, for example. A gum-elastic catheter is then preferable as being less liable to irritate the mucous membrane. By thus habitually relieving habitual retention,

the patient's existence is rendered more tolerable or even comfortable, and life may be considerably prolonged.

When no instrument can be introduced into the bladder, other methods of gaining an entry may be resorted to. They are; forcible catheterism or tunnelling the prostate; puncture of the bladder through the rectum; or puncture above the pubes.

Of these three methods; *forcible catheterism* is recommended by Brodie, Liston, and other Surgeons of large experience; as a safer procedure than puncture through the rectum. The instrument having been thrust through the obstructing portion of the prostate, is left in the bladder for about forty-eight hours, to establish a false passage for its re-introduction.

Puncture through the rectum, and above the pubes, will severally be more appropriately considered and described in stricture of the urethra.

The tendency to *chronic cystitis* as dependent on prostatic enlargement, may be averted; partly by preventing retention, partly by careful regulation of the diet, and the avoidance of exposure to cold or damp, or other causes of any disordered state of the urine, or of determination of blood to the bladder. Remedial treatment is considered in connexion with this vesical affection.

The maintenance of the general health must be conducted on ordinary principles, chiefly of a hygienic character.

**ATROPHY OF THE PROSTATE.**—This prostatic condition is sometimes found in old age, and occasionally in early adult life. The prostate gland is but slightly developed in men whose sexual character is not strongly marked, and in some malformations. No special symptoms or treatment are known.

**CANCER OF THE PROSTATE.**—Cancer occurs less commonly as a secondary deposit, than as a primary disease of the prostate. The form of cancer is almost always encephaloid, and sometimes it is associated with melanotic deposit; scirrhus seems to be of doubtful occurrence.

Age has apparently a certain relation to malignant prostatic disease; it has been observed only in childhood and advancing age. No authenticated cases, observes Sir H. Thompson, are on record between the ages of eight and forty-one.

The *symptoms* are those of prostatic enlargement; but distinguished by the severity of the pain, and its shooting into the rectum, up to the sacrum, and down the thighs; the oft-recurring and more abundant hæmorrhage; and perhaps, constitutional cachexia. The tumour examined through the rectum, as compared with chronic prostatic enlargement, is of larger size, harder and perhaps of irregular shape; subsequently becoming softer and fungating. The adjacent lymphatic glands are affected, both lumbar and inguinal; corroborating the diagnosis. The urine has been said to exhibit under the microscope, characteristic cancer cells; but the resemblance of the epithelial cells, renders this evidence doubtful. Marked rapidity of the symptoms, however, characterizes the malignant disease; its duration from first to last extending only from one and a half to five years in adults, and from three to nine months only in children.

The *treatment* is palliative. Catheterism should be avoided if possible, and then performed with the gentlest touch, not to irritate or injure the part. Anodynes in the form of opium or conium may be administered both by mouth and rectum. Hæmorrhage must be treated as explained in connexion with hæmaturia. The general health and strength will require all the support which can be given by tonics, and a nutritious diet.

**Cysts.**—The substance of the prostate is often beset with numerous small cavities, of an irregular shape, and communicating with the ducts of the glandular structure. They are apparently dilated prostatic follicles. Some such cysts contain several minute concretions or prostatic calculi of larger size, and each occupying a separate recess.

No special symptoms are presented by these small cystiform cavities, and the diagnosis is unimportant, as it would not afford any indication for special treatment.

A cystic condition of the prostate is sometimes met with, resulting from long-continued suppuration with absorption of the glandular substance; and thus forming one large cavity containing pus. The capsule of the prostate has become the pus-secreting sac of an *abscess*.

An *hydatid cyst* has occasionally formed between the bladder, near its neck, and the rectum. This condition is attended with retention of urine and distension of the bladder; simulating the symptoms of prostatic enlargement. The formation of any such cyst within the substance of the prostate seems doubtful.

**TUBERCLE.**—The prostate is very rarely the seat of tubercular deposit, and then always as a secondary affection; some other part of the genito-urinary tract being the primary seat of deposit. The kidney ranks first, and next the testicle. Phthisis pulmonalis is generally associated with the tubercular affection of a genito-urinary organ. Frequent and painful micturition, with some obstruction to the passage of urine, and occasionally slight hæmorrhage, constitute the symptoms. There is also some amount of prostatic enlargement, ascertainable by rectal examination. Subsequently, with suppuration and discharge, the prostate becomes smaller than natural, and the urine purulent. But the absence of special symptoms, and the co-existence of at least a phthisical tendency, will determine the diagnosis.

*Treatment* must be conducted on general principles.

**PROSTATIC CALCULUS.**—The prostate gland, like other glands, is liable to an inspissation of its secretion, forming nuclei around which inorganic deposit and concretion takes place, within the ducts of the follicular structure. This mode of origin, and situation, are characteristic of true prostatic calculus, and distinguish it from urinary calculus which may have lodged in the prostate. Prostatic calculus is composed principally of phosphate of lime, about 84 per cent., with a trace of carbonate of lime; organic matter, 15 per cent., constituting the remainder.

The physical characters of these calculi are peculiar:—their colour is generally a brown chestnut, sometimes black, red, or white; occasionally transparent or like pearl-barley; of softish, or hard consistence; their form is commonly very irregular, faceted, triangular or square; and their size varies from that of granular sand to a poppy-seed or cherry-stone. In point of number, 1, 2, 3, or more, even to 100, may exist, like a bag of marbles. By constant attrition, the facets become smooth and polished. Continued deposition of phosphatic matter at length produces a larger calculus; encroaching on the rectum, or coming forward out of the mouths of the distended prostatic pouches into the prostatic urethra; thence extending forwards, or backwards into the bladder, it forms a prostatovesical calculus. Sometimes one or more prostatic calculi become detached, free and moveable in an open duct. These enlarged calculi have a very irregular or branched appearance.

*Symptoms.*—The symptoms of calculi in the prostate depend on their

situation, size, and number. When small, the symptoms may be absent, or slight. When of larger size, they give rise to pain and weight in the perineum with uneasiness at the neck of the bladder; frequent micturition, sometimes retention of urine, and difficulty in the emission of semen; mucous deposit in the urine, and occasionally erections of the penis. Such are the symptoms of enlarged and irritated prostate; but there is also the physical character of one or more stones in the prostate; as discovered by urethral or rectal exploration, or both. On passing a sound through the urethra, a distinct grating or click is felt and heard, just before the beak of the instrument enters the bladder; a deeply imbedded calculus may be felt by introducing the finger into the rectum; or by simultaneous examination, the calculus may be felt between the finger and sound. A large number of small calculi communicate to the finger a crackling or grating sensation, like that of small marbles in a bag.

Suppuration of the prostate sometimes ensues, forming abscesses.

*Treatment.*—When the calculi are small and free, they admit of extraction by a properly constructed forceps, such as Weiss's long urethral forceps or Weiss's canula forceps. But if the calculi are numerous and not to be felt through the urethra, this procedure will be impracticable; and palliative treatment only can be employed to subdue irritation and relieve retention by occasionally using the catheter.

When the calculi are large, single, or at most only two or three in number; median lithotomy should be performed, and the calculus removed with scoop or forceps. A larger-sized calculus may necessitate the lateral operation.

If there be no urgent symptoms, the case may be wisely left alone.

Urinary calculus or fragment, which has lodged in the prostate, should be extracted by urethral forceps; or, that procedure failing, it may be pushed back into the bladder and then dealt with.

Prostatic and vesical calculus co-existing, both can be removed by the lateral operation.

## CHAPTER LX.

### DISEASES OF THE URETHRA.

THE urethral canal is liable to; (1) Inflammation or Urethritis, and its more specific form, Gonorrhœa; (2) Stricture or contraction of the canal, in some part or parts of its extent; as a structural or organic and permanent condition, or as a spasmodic, or an inflammatory state; (3) Tumours occasionally; (4) Urethral Calculus.

The results of Urethral obstruction comprise;—Retention of Urine; Extravasation; Rupture of the Bladder; and Urinary Fistulæ;—penile, scrotal, perineal, urethro-vaginal, and the associated vesico-vaginal fistula.

*URETHRITIS.*—*Simple* inflammation of the urethral mucous membrane is of not uncommon occurrence, and in either sex.

*Symptoms.*—Heat, pricking, and tension in the urethra for a day or two, are accompanied by some scalding sensation in passing water,—ardor urinæ; and soon followed by muco-purulent urethral discharge. The only symptom may be this whitish discharge; unaccompanied with ardor urinæ, and inflammation.

In the former or *active* condition, the diagnosis from gonorrhœa, is extremely difficult; in the latter or *passive* condition, the distinction is more obvious; resembling gleet, it differs in the thicker and more opaque character of the discharge. The causes of simple urethritis differ also from that of gonorrhœa, which arises from a specific contagion; though here it must be confessed, the line of distinction is even less definite.

*Causes.*—Certain constitutional causes; gout, rheumatism, scrofula, and the use of particular medicines, as guaiacum or Cayenne pepper; frequently induce urethritis. These causes seem to affect the urethra by morbid states of the urine, as when it is loaded with lithic or with oxalic acid; thus producing *direct* irritation in the passage of such urine. They give rise to the active form of urethritis, and the discharge disappears immediately upon the development of the constitutional disease. *Distant* irritation, as gastric derangement, worms in the intestines, or teething, may also excite an urethral discharge; but this is of the passive character.

Local causes of various kinds are not unfrequently the occasions of urethral irritation; as the passage of instruments, sexual intercourse, or the introduction of vaginal discharges,—such as the menstrual fluid, leucorrhœal matter, &c. Here again, the discharge is generally passive.

It, therefore, becomes most important from a medico-legal point of view, to attribute an urethral discharge to its right cause. In young children, the existence of vaginal discharge is not absolute evidence that a rape has been committed. And in persons who are subjects of stricture and irritable urethra, a discharge apparently gonorrhœal sometimes exists, or appears after sexual intercourse, or even after sexual excitement, a debauch, or other stimulant affecting the urethra.

The duration of the symptoms is not nearly so long as in gonorrhœa; simple urethritis usually subsiding at the end of a week or ten days. Chronic discharge not unfrequently becomes established in gouty persons, or in conjunction with stricture.

*Treatment* consists in removing the cause of irritation, and in mild antiphlogistic measures. Thus, saline aperients of bicarbonate of potash and sulphate of magnesia, combined perhaps with colchicum, will often succeed in subduing the inflammatory symptoms. At the same time, a moderate and non-stimulating diet must be observed. Then, when the discharge has become passive, weak astringent injections, as of the liquor plumbi diacetatis, alumi, or sulphate of zinc, will gradually arrest the urethral secretion and complete the cure. I never use the two latter forms of astringents. Copaiba, cubebs, or both mixed, are also administered in this state of the discharge; but I do not find it necessary to have recourse to these agents.

When urethritis is conjoined with stricture, temporary retention of urine may ensue, partly of a spasmodic character. In addition to antiphlogistic treatment; opiates, opiate suppositories, and the relaxing influence of warm hip-baths occasionally, will generally overcome the obstruction. Catheterism should be avoided until relief cannot be obtained without it.

*Gonorrhœa or Blennorrhagia.*—This form of Urethritis is accompanied with a muco-purulent discharge; and is generally produced by contagion or contact with a *similar* discharge, usually during sexual intercourse. It may affect either the male or female.

In the *male*, the urethra is the seat of gonorrhœa, and especially the anterior portion as far as the fossa navicularis within the glans penis; but the urethral inflammation may extend backwards along the whole length

of the canal, particularly affecting the bulbous portion; and even involve the whole mucous membrane of the bladder, in extreme cases. When the inflammation has become chronic, the bulbous portion of the urethra is more especially affected, the intermediate anterior portion up to the fossa is comparatively unaffected. Other portions of the genital mucous membrane may be *secondarily* involved, as that of the prepuce and glans.

*Symptoms.*—Commencing usually from the second to the fifth day after exposure to contagion, or sometimes, though rarely, at later dates; the progress of the disease may be divided into four tolerably definite stages:—(1) The period of irritation; (2) that of Inflammation, acute; (3) chronic or declining; (4) gleet, a chronic state of peculiar discharge which does not always supervene.

*Urethral irritation.*—This stage is characterized by very slight symptoms; an itching or tickling sensation in the meatus, its lips are florid red, puffed, and glued together by a scanty, viscid, clear and colourless or slightly opalescent secretion. Some smarting is experienced in passing urine, but no scalding,—no ardor urinæ. The duration of this stage varies from a few hours to two or three days.

*Acute inflammation.*—The discharge has become an abundant, thick, opaque and greenish-yellow pus; and scalding pain is felt in passing urine, which is voided with difficulty in a diminished or forked stream, or in spasmodic jerks, and with increased frequency. The whole glans is swollen and of a bright cherry-red colour, the course of the urethra is swollen and cord-like to the touch, the prepuce may become œdematous, and the whole penis looks and feels turgescient. When the bulbous portion of the urethra is affected, weight in the perineum will be experienced; and if the prostatic urethra be involved, there will be weight about the anus.

*Chordee* not unfrequently occurs, a painful arching or twisting of the penis downwards during erection; to which there is an involuntary tendency, especially when the patient becomes warm in bed. Thus sleep becomes much disturbed. This bent position of the penis in erection, seems to be the result of the in-extensibility of the corpus spongiosum, owing to the lymph effusion around the urethral canal. When, therefore, erection occurs, this corpus spongiosum not yielding to the distension of the corpora cavernosa, it acts like the string of a bow and bends the penis downwards. Another explanation of chordee is, that it arises from spasm of the muscular fibres which surround the whole course of the urethra.

The characteristic discharge and scalding in micturition, constitute what is vulgarly called the “clap” in England, and “chaude-pisse” in France. Inflammatory feverishness sometimes accompanies this acute inflammatory stage of gonorrhœa, especially in conjunction with chordee; often, however, there is little constitutional disturbance. This stage lasts from one to three weeks; its continuance depending on the number of previous attacks and the habits of the individual.

*Chronic Stage.*—The inflammation having risen rapidly to its highest degree of intensity, now gradually declines;—the discharge of pus slowly subsides again into muco-pus, less abundant and thinner; and the scalding reverts into smarting, or soreness only in micturition. This stage terminates under treatment, in about another three weeks; but it is liable to be prolonged by recurring inflammation under adverse circumstances. Gonorrhœa rarely terminates spontaneously, in less than three months; though change of air, to the sea-side in particular, will often finish off a

slight urethral moisture at an earlier period. The general health undergoes a marked depression during the continuance of gonorrhœa; the patient acquiring a remarkably pallid, listless appearance.

*Gleet.*—Blennorrhœa or gleet must be regarded as the sequel, rather than the concluding stage of gonorrhœa; for it does not invariably occur. It signifies an urethral discharge, scanty, thin, nearly clear and colourless, of muco-purulent character; but unaccompanied with scalding in micturition or other inflammatory symptoms, and persistent,—lasting for months or even years. Thus we speak of an old-standing gleety urethral discharge. It may be maintained by certain constitutional conditions; a scrofulous, rheumatic, or gouty diathesis; a lymphatic, weakly, temperament; or a state of debility. The *contagious* character of a gleety urethral discharge is always more or less persistent; and it is even liable to be developed into a more virulent puriform secretion by slight exciting causes. Sexual intercourse, therefore, is unsafe, so long as *any* discharge exists.

The *diagnosis* of gonorrhœa from simple urethritis has already been noticed. No positive distinction can be drawn from the appearance of the discharge, its contagious nature, or from its having been produced by contagion. As Ricord truly observes, "Gonorrhœa often arises from intercourse with women who themselves have not the disease;" and Diday affirms yet more explicitly; "that from the very fact of a woman having a discharge, no matter what its origin, she is liable to give a discharge to a man."

*Causes.*—Gonorrhœal virus or matter, and occasionally any other discharge, as menstrual fluid or leucorrhœal matter; may severally communicate or give rise to gonorrhœa. Either matter may be the source of contagion, and produce true gonorrhœa in a man. The causative distinction between gonorrhœa and simple urethritis, as formerly held in virtue of the *specific* character of gonorrhœal pus, is now generally acknowledged to be no longer tenable. The contagious character of gonorrhœal pus is more virulent, and the symptoms produced are generally more severe; but the only real ground of distinction is that simple urethritis arises from other causes,—constitutional and local, as well as from any contagious discharge.

The following additional practical facts, although not perhaps exclusively characteristic of gonorrhœal contagion, appear to be well established; 1. The disease is not communicable by sexual intercourse *before* the discharge appears. 2. After the discharge is established, if the urethra be previously washed out by means of a syringe, the disease will probably not be communicated. 3. The matter retains the power of infection for an indefinite period; in one case Titley records that a girl communicated the disease immediately on leaving the Magdalen Hospital, after a seclusion of one year; and in another case, according to Hunter, after two years' seclusion. 4. With gleet, two persons being thus affected, may have intercourse with impunity, but either of them will communicate gonorrhœa to a sound person. 5. The violence of the symptoms depends on constitutional conditions, as the gouty diathesis, and habits of life, as intemperance; thus the same woman may give a very mild gonorrhœa to one man, and a most severe one to another. 6. The first attack of the disease is generally the most severe; a kind of urethral tolerance of the disease being commonly found to follow repeated attacks. 7. The severity and the continuance of gonorrhœa are often inverse; it is most severe in

young and plethoric persons, in the gouty or rheumatic diathesis, and in first attacks; but most obstinate in serofulous and phlegmatic constitutions, in persons affected with chronic skin diseases, and after repeated attacks. 8. The disease seems to be much milder now than formerly.

The generation of gonorrhœa *de novo* is an open question; many apparent causes of origin are rendered very doubtful by the persistently contagious character of even a slight gleet discharge.

Gonorrhœal virus differs entirely from syphilitic virus, as shown by the test of inoculation; neither disease being capable of reproducing the other under any circumstances. They are not convertible diseases.

COMPLICATIONS.—Several morbid conditions of the urethra or of adjoining parts may occur in conjunction with gonorrhœa, as complications of this disease.

1. *Chordee*, a bent and painful erection of the penis, has been already noticed.

2. *Irritation or actual inflammation of the urinary organs*, is apt to occur; sometimes of the deeper portion of the urethra, producing great pain in the perineum, with spasm of the accelerator and other muscles during micturition; thus interrupting the stream of urine, or amounting to complete retention; sometimes of the bladder, causing frequent and painful micturition, the pain continuing for some time afterwards, together with a mucous deposit in the urine; or there may be symptoms of renal irritation, marked by pain in the loins, shivering, vomiting, and albuminous, bloody or purulent urine. This state, with or without symptoms of cystitis, is likely to be induced by early or strong injections, want of rest, indulgence in spirituous liquors, or the use of copaiba in large doses.

3. *Hæmorrhage* from the urethra, from rupture of some of the distended vessels during violent erections, or in *chordee*. The loss of blood is rarely considerable, and generally gives relief.

4. Inflammation and suppuration of some of the *mucous follicles* of the urethra, leading to obstruction; until the abscess bursts into the urethra, or externally, or in both directions.

5. Inflammation of the *inguinal lymphatic glands*, constituting *sympathetic bubo*. This complication occurs generally during the second or inflammatory stage of gonorrhœa. Such buboes rarely proceed to suppuration, unless when subjected to irritation, or in persons of a strumous and debilitated constitution. The lymphatics along the dorsum of the penis may also be affected.

6. *Balanitis or gonorrhœa externa*, is an inflammation of the mucous membrane of the glans and prepuce, attended with profuse, thin opalescent discharge, and excoriation. It occurs mostly in persons who have a long prepuce. And it may be induced by want of cleanliness, hot weather, or by disordered health.

7. *Phymosis* and *Paraphymosis* are terms applied to two exactly opposite conditions of the prepuce, relative to the glans penis. In the first, the prepuce cannot be retracted, or not easily, behind the glans, so as to uncover it; in the second, the prepuce cannot be drawn forward from behind the glans, so as to cover that part of the penis. Both preputial conditions arise from swelling of the prepuce and glans.

8. *Herpes præputialis* is characterized by the appearance of small vesicles, containing an opalescent fluid; and arranged in clusters of two, three, or four, upon the internal or external surface of the prepuce. Other cutaneous eruptions, chiefly roseola, pityriasis, and psoriasis, may

be severally, concomitants of gonorrhœa; appearing, usually, from six weeks to three months after its commencement.

CONSEQUENCES OF GONORRHŒA.—1. Inflammation of the testicle, commencing as epididymitis and resulting in swelled testicle; 2. Gonorrhœal Rheumatism, and the two forms of ophthalmia,—Gonorrhœal Conjunctivitis, an acute purulent inflammation of the conjunctiva, and Gonorrhœal Scleritis, an affection of the deeper textures of the eye, allied to the rheumatic affection. 3. Prostatorrhœa or chronic inflammation of the prostate gland is an occasional consequence of gonorrhœal inflammation or of gleet. It is characterized by the discharge of a few drops of clear, transparent, or slightly turbid viscid mucus, after micturition or defæcation. This is not semen, as it contains no spermatozoa. Irritability about the neck of the bladder, and sensitiveness of the prostatic urethra in passing an instrument, are concomitant symptoms, with physical and mental languor, or hypochondriacal lowness of spirits.

TREATMENT.—The pathology of gonorrhœa supplies three general indications for its treatment, the *prevention of inflammation*; or its reduction, and then the *gradual suppression of the Chronic discharge*, or perhaps *gleet*. These indications correspond to the several stages of gonorrhœa, and they may usually be fulfilled by the following plan of treatment.

*Urethral irritation*.—During this incipient stage—lasting only from a few hours to two or three days—prevention of the inflammatory stage may perhaps be accomplished by means of “abortive” or “revulsive” measures, which comprise astringent injections, with copaiba or cubebs; but any such agents, if used for that purpose, are hazardous by perchance exciting intense inflammation.

*Inflammation—acute, and chronic*.—From the commencement of true gonorrhœal discharge, reducing, and then suppressive, measures may be employed; their nature depending on the degree of inflammation. In *acute* inflammation,—with an abundant thick opaque, yellow or creamy discharge, and scalding in passing urine; the appropriate treatment consists, in gentle saline, alkaline, aperient medicine, with an unstimulating diet, abstinence from wine, beer, or spirits, rest and recumbency. In *chronic* inflammation,—with a diminished, thinner, clearer discharge, and absence of scalding in micturition; the previous treatment may be discontinued, and followed by; acid, tonic medicines, or perhaps copaiba, cubebs, or both, and astringent urethral injections.

In *gleet*,—with a scanty, thin, clear, colourless discharge, of prolonged duration, and unaccompanied with scalding in micturition; the same suppressive measures will also be appropriate.

In accordance with the foregoing plan of treatment, I have almost invariably prescribed with success, in some thousands of cases; an aperient and alkaline mixture,—containing sulphate of magnesia, in about drachm doses, with a little senna, and the sesquicarbonates of soda and ammonia; in doses sufficient to nearly neutralize the urine. This may be taken three times a day. It may sometimes be desirable, in very acute cases, to add the potassio-tartrate of antimony, in the  $\frac{1}{12}$  of a grain dose. The urine is thus rendered less irritating to the inflamed urethra, while the inflammation itself is gradually reduced by the hydragogue operation of the aperient. By continuing this simple anti-irritant and derivative for about three weeks or more, aided by abstinence from wine, beer, spirits, and stimulating food, such as any peppers or condiments; the inflammation will most probably have *safely* subsided in that period.

The discharge has undergone the characteristic change in quantity and appearance to that of the chronic stage; and the scalding micturition has also subsided, leaving only a smarting or soreness in passing urine. Then, the discharge may be safely suppressed, gradually, by using an injection twice a day, consisting of about  $\mathfrak{z}\text{ij}$  of the liquor plumbi diacetatis to  $\mathfrak{z}\text{ij}$  of distilled water. Other injections may be resorted to; the subnitrate of bismuth and mucilage, x grs. to  $\mathfrak{z}\text{j}$  of water, with a little morphia or belladonna; sulphate of zinc, j gr., gradually increased to iv grs., to  $\mathfrak{z}\text{j}$ ; chloride of zinc, j—iv grs. to  $\mathfrak{z}\text{iv}$ ; nitrate of silver j—ij grs. to  $\mathfrak{z}\text{j}$ ; or the sulphate of zinc and acetate of lead aa. xxx grs. to  $\mathfrak{z}\text{vj}$ , an injection long in use at the old Lock Hospital. In obstinate gleet, the bichloride of mercury may prove successful;  $\frac{1}{4}$  gr. to  $\mathfrak{z}\text{j}$  of water. Any such injection is thrown up the urethra by means of a small glass syringe; and in order that it may be applied only to the affected portion of the urethral tract, the finger may be placed under the urethra, just in front of the scrotum. If the inflammation has extended further back,—to the bulb, this restriction should not be made. Bougies, covered with an ointment of nitrate of silver, or the balsam of copaiba, may be passed along the urethra; but this mode of making topical applications is not in general use. In old-standing gleet, the introduction of a bougie occasionally, even where no stricture exists, is highly beneficial. It should be of sufficient size to occupy the urethra without distension, be passed twice or thrice weekly, and left in for about ten minutes at a time.

The medicinal treatment of chronic suppurative discharge, and of gleet; comprises acid-tonics, of which, the sulphuric acid with decoction of cinchona, is most efficacious; iron, towards the close of the case, to repair the anæmic condition. Such medicinal agents as may be suitable in various constitutional conditions, must be resorted to; as in the scrofulous, rheumatic or gouty diathesis, on which a gleet discharge may seem to depend. Certain medicines have apparently some *specific* influence in arresting the discharge, and especially the two renowned specifics copaiba and cubebs. Neither should be administered when it manifestly disagrees with the system; nor continued on trial beyond a week or ten days, when no beneficial effect has been obtained by that time. Both these specifics are liable to disturb the digestive organs, and produce symptoms of irritation of the kidneys; and copaiba sometimes induces a cutaneous rash, in the form of small red patches, more or less circular, and somewhat resembling ordinary nettle-rash.

Copaiba may be administered in various preparations; in capsule, pill, draught, or extract. The capsule, an envelope or coating of gelatine containing a small bolus of copaiba, is an elegant and convenient preparation; the envelope disguising the nauseous taste and peculiar odour of the balsam. Six or eight capsules may be taken daily. In the form of pill or bolus consolidated with magnesia, copaiba sometimes acts more effectually, a drachm being taken thrice daily; or combined with dilute sulphuric acid, fifteen minims, and mucilage in infusion of roses, as a mixture, this medicinal agent is better tolerated by the stomach. Cubebs may agree when copaiba will not. The dose of the powder is a drachm, three times a day. Both these specifics are sometimes advantageously taken together, in such proportions as to form the consistence of an electuary; of which a drachm will be the dose, thrice daily. I never find it necessary to order either copaiba or cubebs, and have for some years discarded them. Hygienic measures should not be overlooked in conclud-

ing the treatment. The tepid or cold sponge-bath, with friction afterwards, sea-bathing, and open-air life, avoiding exercise on horseback; will often succeed in finishing off an otherwise long lingering case. Smoking should be prohibited.

*Chordee* is best prevented or overcome by the administration, at bedtime, of opium and camphor, j gr. to ij grs., combined in a pill; forming an anodyne antispasmodic. Conium and camphor in pill, I have often ordered with marked relief. Camphor alone may be taken, as directed by Mr. Milton; one drachm of the tincture in water, before going to bed, and repeated every time the patient wakes with chordee. Or, the suppository recommended by Ricord; opium, the watery extract, gr. j, with camphor gr. x; may be introduced into the rectum an hour before bedtime. The patient must avoid supper or any excitement before going to bed, and then bathe the parts with cold water, or preferably with warm for some time until a sensation of faintness is produced; he should lie on a hard mattress, and be lightly covered with bed-clothes.

The other *Complications*, and the *Consequences*, of Gonorrhœa, are severally noticed with regard to their Treatment, under their respective headings, in other sections of this work.

**GONORRHOEA IN THE FEMALE.**—Gonorrhœa is a much less common affection in women than in men. The seat of the inflammation and discharge is more extensive; principally affecting the vulva, or usually in conjunction, the vagina, and even extending to the cervix uteri, as well as invading the urethra. Gonorrhœa of the urethra alone, rarely occurs.

*Symptoms.*—In the vulva and vagina, the symptoms are heat and itching, with redness and swelling; soon followed by a copious, mucopurulent or purulent, and offensive discharge. The anterior wall of the vagina beneath the pubic arch is more especially the source of this discharge. But the muciparous and sebaceous follicles of the vulva become involved and pour out a copious secretion. Duverney's or Cowper's glands, upon either side of the entrance to the vagina, may become the seat of abscess. Excoriation or superficial ulceration is often presented, especially when the disease affects the os uteri.

The *diagnosis* between gonorrhœa and *simple vaginitis* cannot be determined by any one symptom, or combination of symptoms; nor by the appearances of the discharge, or its examination with the microscope. This absence of diagnostic distinction is very important in relation to medico-legal inquiry respecting supposed gonorrhœa in children and young females; who are very liable to simple vaginitis from various constitutional and local causes. Dr. West, Mr. H. Lee, and other writers have drawn particular attention to the equivocal character of the evidence in all such cases; and the diagnosis is scarcely less doubtful in vaginal or uterine discharges at any period of life.

In the *urethra*, gonorrhœa gives rise to no special symptoms; scalding in micturition, indicates that this portion of the genito-urinary mucous membrane is involved.

All the symptoms of gonorrhœa in the female are usually less severe than in the male; but they are generally of longer duration, though the discharge does not commonly pass into gleet.

*Causes.*—Gonorrhœal contagion may be simulated by vaginal or uterine inflammation and discharge, arising from other causes, constitutional and local.

*Complications.*—Inflammatory enlargement of the inguinal glands, and

almost exclusively in cases where the urethra is affected; inflammation of the cavity of the uterus, of the Fallopian tubes, or of the ovaries, the latter corresponding to epididymitis in the male; abscess of the labium, presenting on the inner side. Gonorrhœal rheumatism is a rare occurrence, and gonorrhœal ophthalmia, uncommon.

*Treatment.*—No special remedial measures are requisite, but the topical applications must be made directly to the part affected. Thus, lotions should be applied by means of lint placed well in between the labia, and injections be thrown up the vagina to reach the seat of inflammation. Unless these and similar precautions be observed, the discharge will continue in spite of any remedies, however appropriate in their nature.

### STRICTURE OF THE URETHRA.

The term Stricture of the Urethra signifies an unnatural narrowing or contraction of the canal, at one or more points in its extent. This may occur from three distinct conditions:—(1) Organic deposit in the mucous and sub-mucous tissues, of a permanent character, thence known as Organic or Permanent Stricture; (2) Spasmodic contraction of the layer of muscular fibres encircling the mucous membrane—Spasmodic Stricture; or (3) Inflammatory congestion of the mucous membrane—Inflammatory Stricture. The two latter conditions of stricture are of a temporary character, and are thus further distinguished from the first-named. They often co-exist—spasm and inflammation; and either may be engrafted, occasionally, on organic stricture.

ORGANIC OR PERMANENT STRICTURE. — *Structural conditions.* — Four forms of organic stricture of the urethra may be recognised, according to Sir H. Thompson's accurate observations:—*linear* stricture, in which the urethral canal is obstructed by a thin, membranous septum, having a central aperture; or a crescentic septum, which obstructs a segment only of the calibre of the canal; these forming the "bridle stricture;"—*annular* stricture, a thicker and broader, contracted portion of the urethral canal, as if a piece of cord had been tied around it at one point, leaving the remainder free;—*indurated annular* stricture, a more confirmed contraction, in which the induration extends into the tissues of the urethra to the depth of half a line or a line, but limited in extent from before backwards to less than half an inch of the canal, and presenting an hour-glass contraction, usually thicker on the floor than at the upper aspect of the urethra;—*tortuous* or irregular stricture, owing apparently to adhesion of the rugæ of the urethra, to a short extent, or to a cicatricial patch of induration, or a longitudinal contraction and induration to an extent of one or more inches. In this condition of stricture, the induration may involve the entire substance of the corpus spongiosum, presenting the most obstinate and undilatable form of stricture.

*Situation of Stricture.*—The urethral canal is liable to stricture in three situations:—(1) At the junction of the spongy and membranous portions; or within an inch before, and three-quarters of an inch behind, that point. Of these situations, the most common seat of stricture is the bulbous part of the spongy portion—anterior to the triangular ligament, rarely, behind this membrane, in the membranous portion, and most rarely as far back as the posterior part of the membranous portion. No instance has been found of stricture in the prostatic portion of the urethra. The above strictures correspond to the sub-pubic curvature.

(2) In the centre of the spongy portion, or that portion of the urethra which extends from the anterior limit of the preceeding to within two inches and a half of the external meatus, a length of about three inches.

(3) At the external orifice, and within a distance of two inches and a half of it.

These definitions as to the situation of urethral stricture result from a laborious examination by Sir H. Thompson, of 270 preparations in our principal public museums, and comprising 320 distinct strictures. In region (1) were found 215, or 67 per cent. of the entire number; in region (2), 51, or 16 per cent.; in region (3), 54, or 17 per cent. Mr. H. Smith made a similar investigation of this question, on a smaller scale; the preparations numbering 98, as preserved in the different London museums. Of these, 77 were strictures situated anterior to the triangular ligament; and 21 only, in the membranous portion of the urethra.

*Several* strictures may co-exist in the same urethra; John Hunter records an instance of six strictures in one urethra; Lallemand and other French writers describe seven or eight; Sir H. Thompson has never been able to find any such examples, and he limits the highest number of co-existing strictures to three, or the most four. In the above number of 270 preparations, 8 were cases of stricture in all three regions; 10 in regions 1 and 2 only; 10 in regions 1 and 3 only; 13 in regions 2 and 3 only.

*Symptoms.*—The urethral obstruction occasioned by stricture gives rise to symptoms which are individually, or collectively, significant of this condition. Increased frequency of micturition arises, owing to the inability to completely empty the bladder; the stream of urine becomes smaller than is natural to the individual, and altered in form, either flattened, twisted or cork-screwed, forked, or turned aside; and discharged with a less forcible propulsion, so that the current is not ejected as far from the person as formerly, and at length issues as a mere dribbling or in drops.

As the obstruction *increases*, the muscular coat of the bladder gradually strengthens and hypertrophies, in order to compensate for the difficulty in ejecting the urine through the strictured urethra; and as this thickening of the bladder proceeds, its capacity is proportionably diminished, less urine can be retained, and micturition must be even more frequent. This state, annoying and inconvenient during the day, is distressing at night, when exhaustion would invite to rest; the sufferer being repeatedly aroused from his temporary doze, and the night passed in restless efforts to obtain relief. After each act of micturition is apparently completed, another significant symptom is experienced; a certain portion of urine still escapes as a dribbling leakage, owing to the propulsive force of the remaining urine being insufficient to overcome the resistance of the stricture, which was dilated by the stream passing when the bladder was full. After the act of micturition is actually quite finished, a certain portion of urine can sometimes be squeezed out by pressure behind the seat of stricture, from the dilatation of the urethra in that situation. Pain is usually felt in the canal behind the stricture, during the effort to pass urine; and by constant straining, some feculent matter or flatus escapes at such times, and a tendency to prolapsus of the bowel is established. In a paroxysm of straining effort, rupture of the urethra may occur, behind the stricture; and then extravasation of urine takes place into the cellular texture of the perineum, scrotum, and supra-pubic region. In the act of coitus, much pain is experienced about the ejaculatory

ducts; and, as the semen escapes with difficulty through the urethra but passes back into the bladder, there may be no seminal emission; and the unhappy patient believes himself actually, as he may be virtually, impotent. The urine undergoes those changes which result from chronic cystitis, consequent on retention. It becomes ammoniacal, cloudy, and deposits more or less mucus and pus, with phosphates. Hæmaturia is an occasional concomitant of stricture; the blood coming from the mucous membrane of the bladder, or perhaps from the urethra after catheterism or an erection of the penis affecting the seat of stricture. A gleet discharge not unfrequently attends old stricture of the urethra.

The general health fails, the patient losing flesh and strength; he has an anxious and careworn appearance, suffers from pains in the loins, lower part of the belly, the perineum and testicles; and is subject to severe attacks of rigors. Any irritation of the urethra, as by passing an instrument or the application of an irritant substance, will often provoke such an attack, especially in those who have lived in hot climates, or it not uncommonly excites general feverishness—hence named “urethral fever,” and which has sometimes an intermittent character.

Certain *varieties* of organic stricture may be recognised by some peculiarity of their respective symptoms.

*Simple* stricture; chiefly denoted by diminution in the size of the stream of urine and the other ordinary symptoms of stricture.

*Sensitive or irritable* stricture.—Proneness to disturbance of the nervous system, as manifested by chilliness or rigors on very slight urethral irritation; and pain, sometimes persistent, from the gentlest passage of an instrument. A disposition to hæmorrhage is evinced in a few cases.

*Contractile or recurring* stricture—distinguished by a constant tendency to further diminution of the urethral canal, in the absence of treatment; and contraction recurs rapidly after dilatation has been effected.

*Examination of the Urethra.*—Catheterism supplies the most direct and conclusive evidence as to the existence of stricture; evidence analogous to that of sounding for stone in the bladder. The presence of stricture, its situation, its calibre, the extent of the canal involved, and the amount of induration, may be thus severally determined; and whether also there be one or more strictures. Instruments of various composition and form are used for this purpose; catheters, which may be inflexible as the ordinary silver instrument, or flexible gum-catheters; and bougies which are solid instruments of flexible metal, or flexible and elastic, as the ordinary gum-elastic bougie, wax, or catgut bougies. Generally, an inflexible instrument is to be preferred (Fig. 453); its point taking the

FIG. 453.

direction of the urethra more certainly, and being more accurately under the control of the hand at the other end of the instrument. Catheters and bougies may be curved or straight. The former shape is generally applicable; and the curve most commonly suitable, is that which corresponds most nearly with the bend of the urethra at its inner third—an

arch rather less than one-fourth of the circumference of a circle  $3\frac{1}{4}$  inches in diameter. (See Fig. 453). Straight instruments are preferable only for strictures in the ante-scutal portion of the urethra.

The *bougie olivarie* possesses two advantages; a bulbous or spear-headed end, and flexibility; it can, therefore, be insinuated, or passed with a screw-like action, into a tight stricture, and readily takes the course of an irregular urethra,—without causing pain, hæmorrhage, spasm, or rigors. This instrument, originally advocated by Mr. Teevan, in this country, is now much used.

The *introduction of a catheter* may be performed in either of two ways; in the recumbent position, and with the curve of the instrument directed upwards; or in a standing position, and with the curve of the instrument looking downwards. Of these two methods, the former is usually more easy and convenient both to the patient and Surgeon. The patient lying down on his back, with the shoulders a little raised, the legs thrown easily apart, and slightly drawn up; an instrument of appropriate size—number 7 or 8—is selected, and warmed by a little friction up the sleeve for a few seconds, and then oiled or smeared with lard. In introducing it, the handle should be held lightly between the thumb and the fore and middle fingers of the right hand—the concavity of the curve looking upwards towards the left groin of the patient, and the direction of the instrument being nearly horizontal. Raising the end of the penis with the thumb and finger of the left hand, so as to draw it up to its full length; the double curve of the urethral passage, somewhat resembling an italic *S*, is thus changed into one curve, commencing from just in front of the scrotum; and this single curve corresponds to the curve of the instrument, as it passes along the urethra from that point downwards and upwards into the bladder. The point of the instrument—held as directed—is now inserted into the urethral meatus and carried slowly onwards along the floor of the canal—to avoid the lacuna on its roof, until four or five inches have disappeared; the handle is brought, at the same time, to the middle line, but still parallel and near the patient's abdomen; then it should be gently raised, and as the point of the instrument passes under the sub-pubic curve, the handle is carried forwards and lightly depressed until it sinks below the horizontal line, when the opposite end will turn upwards into the bladder. When the point of the instrument has passed below the scrotum, its further progress in the right direction may be facilitated or maintained, by guiding it between the fore and middle fingers of the left hand, under the pubes; and sometimes, the introduction of the fore-finger into the rectum will aid in determining the middle line onwards to the bladder. Any slight resistance may be obviated by manipulating the instrument, in respect to its direction, or withdrawing it for an inch or so, and then re-passing it. But the presence of *stricture* is determined by an arrest of the instrument point blank, and at the same part of the urethra on each re-introduction. Remembering the situations of stricture, this obstruction will be found usually behind the scrotum, in the sub-pubic curvature; less frequently in the ante-scutal portion of the urethra. No force should ever be used, nothing more than the pressure of a light hand, exercised slowly, and with patience. Any departure from this injunction may lead to perforation of the urethra and the formation of a “false-passage;” and this misadventure is the more likely to happen when the handle of the instrument is being depressed, whereby the shaft acts as a powerful lever on the point in the urethral passage.

The other method of introducing a catheter—when the patient stands upright, is performed in the *opposite* manner to that in the recumbent position. It is the “*tour de maitre*” of French authors. The patient standing with his back to a wall, so that the nates shall not recede during the procedure, and with his legs a little apart; the instrument is introduced with the curve looking downwards, and the handle in a perpendicular line beneath, the penis being drawn straight forward. Having passed the instrument in this direction as far as the sub-pubic arch; it is swept round to the right and raised upon the abdomen, thus describing a semicircle, of which the catheter-point is the centre; then the handle is gradually depressed, so as to carry the point of the instrument through the sub-pubic curve into the bladder.

The *existence* of stricture having been ascertained by the obstruction offered, at some point, to the introduction of a catheter along the urethra; its *situation* may be estimated by feeling the end of the instrument behind the scrotum, or in front as the case may be, and noted more accurately by the length of the instrument passed from the external meatus (Fig. 454). The *degree* of contraction or the calibre of the canal at that point can be estimated by the size, or number, of the instrument used; the *extent* of the canal involved, by the length of the instrument “held” or “grasped” from the point of entering the narrowed portion of the urethra; while, at the same time, the amount of *induration* may be judged of by an experienced tact. A second or third stricture is discovered in like manner, by continuing the urethral examination

FIG. 454.

To complete the examination of any one or more strictures, several instruments, of different sizes, will perhaps be necessary. Five of the sizes in common use, are here represented; the outer circle of each indicating the diameter of the instrument. (Fig. 455.) Number 7 or 8 size should always be tried first; a smaller-sized instrument is liable to hitch in one of the urethral lacunæ, or against the verumontanum, or in the sinus pocularis, as if it were fixed in the stricture; or it might pass through the stricture imperceptibly. Either occurrence would mislead the Surgeon. The smaller the instrument used the greater caution and delicacy must be observed in using it; lest incautiously the urethra be perforated. A soft *wax-bougie* has been recommended with the view of taking an impression or mould of the size and extent of the stricture. Any such supposed advantage is more than neutralized by the difficulty of finding the

FIG. 455.

stricture, as compared with the facility in using an inflexible instrument.

*Causes.*—Two classes of causes may be recognised as resulting in the formation of an organic stricture.

(1) Inflammation of the urethra with *plastic deposit* in the mucous and sub-mucous tissues; thereby glueing together the organic muscular layer which immediately underlies the mucous membrane, and in virtue of which the canal naturally undergoes temporary alterations of calibre, by relaxation or contraction. This kind of cause comprises gonorrhœa; the inflammation extending along the canal, and being of a severe or long-continued character. The symptoms of stricture supervene very slowly and insidiously; a period of many years perhaps elapsing before the existence of this organic constriction is declared. Simple urethritis may have the same result, but only under the operation of some persistent constitutional condition. Injections for the cure of gonorrhœa tend to the formation of stricture; when used in the inflammatory stage, or of too great strength, or long continued. Thus, an injection of nitrate of silver,  $j$  to  $ij$  grs. to  $\bar{3}j$  of water, can do no harm; but in the proportion of  $x$  grs. to  $\bar{3}j$ , it may certainly produce stricture. Abscess in a lacuna of the urethra followed by contraction of the *cicatrix*, is an occasional cause; and cancerous or other ulcers may similarly result in the formation of stricture, usually near the external meatus; amputation of the penis sometimes issues in like manner.

(2) Injury to the urethra by external violence on the perineum, bruising, lacerating, or rupturing the urethra, is followed by a *cicatrix*, the contraction of which may result in stricture of the most severe and intractable character. This kind of cause comprises, blows or kicks on the perineum, falls on some hard projection, as across spars, scaffolding, ladders, chairs, gates, wheels, saddles, &c.; puncture of the perineum, by palisading, by an earthenware vessel breaking under the sitter, &c.; laceration, by pelvic fractures involving the urethra; and lastly, by the forcible introduction of urethral instruments.

*Congenital* stricture is occasionally met with, near the external meatus; in early life, its existence is unattended by any inconvenience; but in adult life, it gives rise to serious obstruction to the passage of urine, when the urethral tissue has become less extensible.

*Consequences, and Terminations.*—The course of stricture is very similar to that of chronic enlargement of the prostate. *Chronic* cystitis or a state of the bladder bordering on it, commonly ensues from the habitual retention of urine and distension of the bladder. The characters of the *urine* are in accordance with that condition. The *general health gradually declines*; as the result of broken rest from ineffectually relieving the bladder, and of constitutional disturbance owing to the state of the organ, aggravated by occasional attacks of *spasmodic retention*; or the constitutional symptoms may be those of increasing *nervous prostration* with oft-repeated rigors, induced sometimes by each act of micturition, or simply by the introduction of an instrument; and *rapid depression* may supervene, either from ulceration or sloughing of the bladder with recurring hæmorrhage, or from profuse purulent discharge. *Rupture of the urethra* is liable to occur, owing to dilatation and ulcerative opening of the canal immediately behind the stricture; followed by *extravasation of urine* with its attendant symptoms. Rupture of the *bladder* is a very rare event. Both these consequences of Stricture are dependent on Retention of Urine,

and they will be noticed under the head of Extravasation of Urine. *Suppression of urine*, with uræmia, sometimes occurs from slight urethral irritation; as by the introduction of an instrument only one size, or number, larger than that to which the patient is accustomed, or in consequence of a slight urethral abrasion, or from the mere passage of an instrument. Severe rigors and suppression of urine are both far more apt to occur when disease of the kidneys exists, so that the one becomes a tolerably sure indication of the other; and the fatal issue is more rapid and inevitable.

Certain *pathological conditions* of the urethra, bladder, ureters, and kidneys, result from the mechanical effect of long-continued retention of urine. They are discovered *after death*. The *urethra* becomes contracted in calibre before, and dilated sometimes into a sacculus just behind, the seat of stricture. In the latter, or dilated pouch, sabulous matter and even calcareous concretions, occasionally collect. Rupture of the urethra may have taken place in this dilated portion; and in connexion with an abscess, usually perineal. The ejaculatory ducts also, opening into the sinus pocularis, are liable to become enlarged. The *bladder*, subjected to the constant backward pressure of urine, which distends its cavity, becomes fasciculated internally, and perhaps sacculated; the one alteration of this organ representing an hypertrophied state of its muscular bands, the other, intervening protrusion of the mucous membrane. The general result is a diminution in the capacity of the bladder for the retention of urine. (Fig. 456.) Rupture of this organ may have occurred, though very rarely. The *ureters* have undergone dilatation by the tendency to reflux of urine, and the pelvis of these tubes may be much enlarged; the *kidneys* also have become more or less atrophied in their pyramidal and cortical portions, resulting perhaps in sacculated remnant kidneys, or in the formation of mere bags. Hence, the suppression of urinary secretion, and uræmic blood-poisoning. Sometimes, the bladder may have ruptured under prolonged retention of urine, in consequence of a small pin-hole aperture of ulceration in the mucous membrane of one of the sacculi.

*Treatment.*—The object of treatment is two-fold; to restore the urethral canal to its natural calibre, and to maintain that state of patency.

But for the accomplishment of this object, different modes of treatment are necessary according to the various states of stricture; its degree of contraction, and induration, its dilatability, its sensitiveness and proneness to disturbance of the nervous system, its contractility and disposition to recurrence. All the modes of treatment may be reduced to four; (1) Gradual Mechanical Dilatation; (2) Immediate and Forcible Dilatation,

FIG. 456.

or Rupture; (3) Caustics; (4) Division of the Stricture, either by internal urethrotomy, or by external urethrotomy,—usually perineal section.

GRADUAL MECHANICAL DILATATION,—inducing absorption of the plastic deposit around the seat of stricture. This method of treatment is most generally applicable; the other methods being resorted to when it proves ineffective, or when it is contra-indicated by one of the adverse states of stricture above mentioned.

The *instruments* used for gradual dilatation are catheters, sounds, and bougies,—inflexible, or flexible and elastic; and always of gradually increasing size. Metallic instruments will be preferable in most cases, and none are more effective than the ordinary silver catheters.

The selection of an appropriate instrument, in respect to its size and curve, will depend on the degree of contraction and the situation of the stricture; both these points having been determined by urethral exploration with a catheter, sound, or bougie, as already explained in completing the diagnosis of stricture. A catheter is generally preferable even for *that* purpose; for not unfrequently the patient first seeks relief when suffering from an attack of retention, and the Surgeon having succeeded in getting an instrument into the bladder, may be very glad to leave it there.

The introduction of a catheter may be performed in either of the two ways already described; and according to the directions given. An instrument of such size only should be used as shall be found to enter the stricture easily, and can pass fairly through it without feeling tightly held by the contraction. Dilatation is then effected by leaving the instrument in this contracted portion of the canal; so as to continue the slight expansion, and induce absorption of the plastic deposit in the mucous and sub-mucous tissues forming the stricture. The *period* for maintaining the dilatation is about five minutes,—some say twenty minutes; then the instrument should be withdrawn, and its size, or number, noted, as a standard of comparison in the subsequent introduction of gradually larger-sized instruments. This procedure should be *repeated* every two or three days. But the intervals of catheterization must be regulated by the state of the urethra, and the constitutional disturbance induced. When bleeding, pain or smarting in micturition, follow or continue after the operation—events very likely to happen after the first passage of an instrument through the stricture; further dilatation must be postponed for a day or two, until this urethral condition has subsided. Shivering, faintness, or sickness, may also supervene, especially under similar circumstances; postponing any re-introduction of an instrument until this state of constitutional disturbance has passed off. Chloroform, therefore, often becomes an invaluable agent in the treatment of tight stricture by dilatation.

This plan of treatment must be prolonged until the urethral canal is restored to its natural size, and the stream of urine fully established. The urethra may then admit a catheter of full-size,—number 12, with ease; when it should be passed less frequently, once in a week or ten days. Lastly, it will be necessary to maintain the patency of the canal, by an occasional use of the instrument once in a month or six weeks.

In the course of treatment by gradual dilatation, the general health should be attended to; especially with regard to the digestive organs, and the state of the skin and kidneys.

*Continuous* dilatation may be advantageously resorted to when the stricture proves obstinate under the ordinary plan of gradual dilatation. The principle is that of rapid dilatation and dissolution of the stricture,

by retaining the instrument in the contracted portion of the canal for a period varying from forty-eight to seventy-two hours, at a time. The catheter is fastened by means of tapes passed through the eyes of the instrument, on either side, and thence under the buttocks and over the thighs to a waist-band. If a gum-catheter be used, it can be secured by a strip of adhesive plaster to the penis. A peg of wood or bit of cork is inserted into the orifice of the catheter, and the water drawn off as occasion requires.

In the management of this process, three points must be observed:—the catheter should occupy the stricture, without fitting tightly or being grasped by it; the instrument, when tied in, should not project against the interior of the bladder; and after using a silver instrument on the first occasion, the succeeding instrument may be gum-elastic, as causing less irritation.

When, in about forty-eight hours, the catheter has become loosened in the stricture, and a slight purulent discharge has taken place around the instrument; it should be withdrawn. In two or three days, this procedure is renewed, and an instrument larger by two or three sizes may be at once introduced; and so on until a full-sized one can be passed easily. Re-contraction must then be prevented by occasionally passing an instrument, at gradually increasing intervals of time.

*Difficulties and Accidents in Catheterism.*—*Induration* or hardening of the stricture sometimes presents considerable difficulty to insertion of the point of the instrument. This may perhaps be overcome by using a conical-shape pointed catheter. But, if the stricture be not very sensitive, continued pressure on the face of the induration will probably cause the stricture to yield. Injecting the urethra with four or five drachms of olive oil seems to exercise an hydraulic pressure on the stricture by penetration of the fluid into the narrowed passage.

*Spasmodic* action must be overcome by the means appropriate for spasmodic stricture.

*False passage.*—A false passage, or a passage leading out of the natural urethral canal, is made by forcible and misdirected pressure with the point of any instrument in its course through the urethra. The passage, therefore, usually takes a direction downwards and backwards, and to one side of the urethral passage; in an opposite direction to the stream of urine, the free discharge of which remains unaffected. An inflexible instrument, as the ordinary silver catheter, will be more apt to cause misadventure than a flexible instrument; but the latter is more liable to enter a false passage already existing.

The previous existence of such a passage or passages is perhaps the most common and perplexing occasion of difficulty in using an instrument; and its production, an accident most to be avoided. The importance of these considerations in relation to catheterism, lies in the fact that the difficulty of entering the right opening, is increased by the facility with which the instrument slips into the wrong one.

A false passage varies in its *situation* and *extent*. When the stricture is far forwards, the passage may run in the corpus spongiosum; when further backwards, in the usual situation, the passage may perforate the lateral lobe of the prostate or run up between it and the rectum; this latter direction being especially dangerous. The *floor* of the urethra is most commonly the seat of a false passage; and it is most liable to happen in connexion with a tight stricture, and the introduction of a small-sized instrument. Hence, in the treatment of such a stricture more particularly, and when it has been subjected to the previous use of instruments;

an important practical injunction in passing the catheter is this,—the point of the instrument should be kept against the roof or *upper surface* of the urethral canal.

Certain *signs* at once indicate to the Surgeon that a false passage has been commenced, or entered if pre-existing. The point of the instrument is felt to make a sudden slip, and the shaft inclines to one side of the urethra; the point also feels free and moveable, and communicates a rough or grating sensation, while it can be easily withdrawn; all these peculiarities being more notable when occurring after the instrument had been felt to be held or grasped by the stricture. The patient experiences sudden and severe pain, and is often conscious that something has given way; on withdrawing the instrument, it is found besmeared with blood, and there will be free hæmorrhage from the urethra.

*Hæmorrhage* must, therefore, be regarded as another accident attending catheterism; but it is also liable to occur independently of any urethral lesion, from the mere passage of an instrument, in inflammatory stricture.

*Inflammation* affecting the urethra or testes may be induced by dilatation; especially with instruments of too large a size, or rapidly increased.

Other evil concomitants, or consequences, have already been alluded to; pain in micturition, rigors, faintness, sickness.

Gradual dilatation having proved ineffective for the cure of stricture, other methods of treatment must be resorted to; and they are especially applicable, when either the sensitive state of the stricture or its contractile and recurring tendency would render that mode of treatment inapplicable, as being intolerable or unsuccessful. The degree of tightness of the stricture and the amount of induration, together representing an undilatable state of stricture, will be found to determine the particular mode of treatment then appropriate;—whether Forcible Dilatation or Rupture, or Division by incision, internally or externally.

**IMMEDIATE AND FORCIBLE DILATATION, OR RUPTURE.**—In estimating the applicability, and advantage, of this method of treatment for stricture of the urethra; it would certainly appear that the vital character and constitutional relations of the urethral tube should forbid any dilatation of an immediate and forcible character; and still more so any rupture of its component tissues. Yet experience has now shown that not only may this mode of treatment be practised with impunity; but, that a tight stricture undilatable gradually, beyond a certain degree, and any further distension of which would excite severe constitutional disturbance, may be forcibly dilated or ruptured up to the natural size of the urethra and without producing any such symptoms.

Forcible dilatation is effected by means of *distending instruments*, which when passed through the stricture exert an expanding force from within outwards. Such force may be accomplished by a *series* of instruments, consisting of sliding tubes, passed successively over a slender urethral director or guide, which is first passed through the stricture; or, it may be effected by means of a *single* instrument which expands *in situ*.

*Sliding tubes* were originally employed by Desault (1797), and afterwards by Dr. Buchanan of Glasgow (1831), Dr. Hutton of Dublin (1835), and by Maisonneuve (1845). Mr. Thomas Wakley, of the Royal Free Hospital, with whom this mode of treatment was originally identified in this country, contrived a series of accurately-fitting tubes and an urethral director. This having been first passed through the stricture, each sliding-tube, in succession, cannot fail to take the same course. The

difficulty, and the risk, will always be to first introduce the slender director through a tight stricture; a difficulty proportionate to the degree of contraction, and the existence of false passages, or the liability of making them. *Single* instruments of various kinds have been devised, which expand *in situ*, in the place of several instruments of increasing calibre: and thus save the necessity of passing them successively through the constricted part of the urethra. With this object, Mr. Luxmore (1812) employed diverging metal rods; Leroy d'Etiolles the same method, some years later, and Perrève a somewhat similar plan (1847). Dr. Neil Arnott, on the same principle, commenced the employment of fluid expansion (1819). Both these forms of contrivance,—the series of sliding-tubes and the single expanding instruments, have a similar action upon the urethra,—distension of the contracted portion from within its area. They thus differ from the large conical metallic bougie formerly used for the purpose of forcible dilatation, which was driven into the stricture; thereby running the risk of pushing the stricture down the canal and detaching its connexions, and inevitably inducing inflammation and severe constitutional disturbance.

*Rupture or Splitting of the Urethra.*—Mr. Holt has recently revived this mode of forcibly opening stricture of the urethra. It seems to be most applicable to tight stricture, without much induration; so that the plastic deposit does not form a mass too thick or dense to be entirely ruptured. Rupture may, therefore, possibly supersede the necessity for division by a cutting operation.

The “dilator” used by Mr. Holt is precisely similar to that of Perrève. Its construction, and his mode of operating, he thus describes:—The instrument consists of two grooved blades fixed in a divided handle, and containing between them a wire welded to their points; on this wire a tube—which when introduced between the blades corresponds to the natural calibre of the urethra—is quickly passed, and thus ruptures or splits the obstruction. Having introduced it, and reached the bladder, the dilator should be gently rotated, to prove that it is fairly within that viscus; and being thus assured, the Surgeon is next to place the point of the tube he had previously selected, upon the wire between the blades, and thrust it quickly onwards to the end. The stricture being now fairly split the dilator should be rotated, to still further separate the sides of the rent, and then be withdrawn; a catheter corresponding to the number of the tube being substituted for the purpose of removing the urine. The catheter is then withdrawn, the patient treated with quinine and opium for the first twenty-four hours; and the same catheter introduced in forty-eight hours; and again on alternate days for a week or two, gradually lengthening the interval.

The *results* of this procedure in the hands of Mr. Holt have been eminently successful; and the experience of other Surgeons has generally confirmed its value. I have not seen much constitutional disturbance follow the operation of splitting the urethra; but in one case, operated on in another Hospital, extravasation of urine ensued, for which I treated the patient at the Royal Free Hospital, and he recovered. Many deaths, however, have I believe ensued,—Mr. Teevan says fifteen in number, which have not been recorded in the Reports of Cases hitherto published. It would also be very desirable to diagnose more correctly the *pathological conditions* of stricture operated on,—if indeed they can always be determined clinically; since it will be obvious that the mere splitting up a number,

say some scores, of urethræ, many of which were perhaps scarcely strictures at all, can have nothing to do with the propriety or eligibility of this mode of treatment. The splitting of urethræ, in almost a *healthy* state, would necessarily swell the resultant proportion of, apparently, successful cases.

Sir H. Thompson has contrived a *distending* instrument for this operation, and which seems to possess three advantages:—distension of the stricture alone is accomplished, without involving the healthy portion of the urethra in its action, the distension can be carried to a calibre of 14 or 16 of the catheter scale, beyond the size which the external meatus will admit, and is thus more efficient; and the distending force is applied very slowly, continuing from seven to ten minutes before reaching the maximum point of distension,—the object being to overstretch the morbid tissues as much, and to rupture them as little, as possible, in order to destroy, or greatly impair, the natural tendency of the stricture to undergo contraction.

CAUSTICS.—Cauterization, in the treatment of stricture, has been practised with two objects in view; the destruction of induration, and the deadening of sensibility or spasm; in both ways permitting subsequent recourse to dilatation. It may be effected by the introduction of an instrument armed with caustic, such as nitrate of silver or potassa fusa, which is carried down to, and allowed to rest against, the stricture, for two or three minutes. A gleet discharge is thus established, and the caustic re-applied every two or three days until a catheter can be passed, and gradual dilatation made to complete the cure.

This method of treatment was formerly in vogue, and still, I believe, has one or two advocates in this country; but the experience of the best Surgeons both here and in France has condemned it, as being both perilous, and extremely uncertain in its results. Stigmatized by Mr. Liston, as “most atrocious,” and discountenanced more recently by Nélaton; the cure of stricture can always be accomplished more safely, and with greater probability of non-recurrence. Cauterization has, therefore, now fallen into general disuse.

DIVISION OF THE STRICTURE.—Section of the urethra may be appropriately resorted to in tight stricture, with considerable induration; forming perhaps a large and hard nodule, unfitted for rupture. This can be effected by incision; either from within the urethra; or from without, and usually in the perineum.

(1) *Internal Urethrotomy*.—Division of the stricture from within the urethra, has been practised for above a century. Allies of France (1755); Physick of Philadelphia (1795), John Bell (1806), and his brother Charles Bell (1807), McGhie (1823), and Stafford (1827); have severally advocated this method of treatment. It has been practised extensively in France, especially by Civiale; and occasionally by modern Surgeons in this country.

The operation may be performed in two ways;—*incision from before backwards*,—section being made by pushing downwards a lancet-like blade, generally with a slender conductor in advance of it, into the obstruction to be divided; *incision from behind forwards*,—a portion of the instrument containing a small blade, sheathed, is first carried down through the stricture, which is then divided by protruding the blade and withdrawing it through the whole of the contracted portion. Various instruments, or *urethrotomes*, have been constructed for the internal division

of strictured urethra. Stafford's lancet-catheter (Fig. 457) may be used; the point, indicated by the dotted lines, is concealed in the tube until the end of the instrument rests upon the stricture, it is then projected through the obstruction. A curved, as well as the straight form of this

FIG. 457.

instrument, has been employed. For incision from before backwards; Sir H. Thompson's catheter-urethrotome, or Mr. John Wood's instrument, are applicable; for incision from behind forwards, Civiale's urethrotome is the best form of instrument. After either mode of operation, a full-sized catheter must be introduced, and retained for twenty-four hours. An instrument should also be passed occasionally, for some time, to prevent re-contraction.

The results of internal urethrotomy are satisfactory as regards the immediate restoration of the urethral canal to its natural calibre; the ultimate result may be permanent, or evince a tendency to the return of stricture,—generally, however, amenable to dilatation. It should also be observed that in both modes of internal urethrotomy, the strictured portion of the canal must be already sufficiently large to admit an instrument, equal in size to a number 4 or 5 catheter; and that with this degree of patency, it may well be considered probable that further and perhaps complete enlargement can be accomplished by dilatation.

(2) *External Urethrotomy*.—Division of the stricture by external incision is an alternative operation of urethrotomy, the earliest instance of which for the cure of stricture, is recorded by Wiseman (1652). A few years afterwards, Solingen, at Livourne, adopted this procedure; followed by François Tolet and Colet (1690). J. A. Petit, and Ledran (1740), had recourse to a similar operation; and John Hunter (1783), performed the operation now known as the perineal section; but it was rarely employed until advocated by Mr. Grainger of Birmingham (1815), and afterwards by Mr. Arnott. These operations refer to cases in which no instrument could be passed through the stricture. More recently (1844), Mr. Syme has advocated external division of the stricture in cases where, although a catheter can be passed, no other treatment has afforded sufficient or permanent relief.

*Perineal section*, as the operation of external division of the stricture may be generally designated, is applicable in two degrees of extreme urethral contraction:—permeable stricture, through which a slender grooved staff can be passed, and the external incision made upon this instrument; and impermeable stricture, through which no instrument apparently can be passed, the only guide being a full-sized instrument passed down to the stricture, towards the point of which the external incision is directed.

The condition of stricture appropriate for perineal section, is that of considerable, even cartilaginous, induration, both in thickness and extent, appreciable usually by external examination with the finger; coupled perhaps with perineal fistulæ, either chronic or numerous.

(a) *Permeable Stricture*.—Perineal section, by Syme's operation, is

performed as follows:—The instruments required are; a staff, slender, slightly curved, and well grooved in its lower half, and the upper of full size; a pointed scalpel, a broad director, and a silver catheter, number 8, or 10. The staff is passed *through* the stricture, so that the shoulder or termination of the upper thick portion rests against the upper part or face of the stricture. The patient is tied up as for lithotomy, and the staff held in like manner by an assistant, with the scrotum drawn forwards. The Surgeon, sitting in front, makes an incision in the raphé or median line of the perineum, about two inches in extent, and proceeds cautiously straight to the shoulder of the staff; feeling his way with the fore-finger of the left hand. Having clearly reached that point, he takes the staff from the assistant in his left hand, and enters the point of the knife in its groove, *behind* the stricture; thence cutting upwards to the shoulder of the instrument until it can be passed onwards into the bladder. This instrument is then withdrawn, and the number 8 catheter introduced and retained for forty-eight hours. Subsequently a full-sized catheter should be passed every three or four days, and afterwards at longer intervals, to prevent re-contraction. Difficulty in introducing the catheter, after withdrawing the staff, may be obviated by first passing the director into the urethral wound, along which, as a guide, the catheter glides into the bladder. Instead of using a catheter, Mr. Syme prefers at first to pass a tube through the wound into the bladder in order to guard the wound as much as possible from contact with urine.

The following directions are given by Mr. Syme, as essential to the success of this operation:—1. Maintain the median line in the incisions. 2. Make a direct opening down to the staff, not a tortuous one. 3. Divide the whole of the contracted part, rather more than less. 4. Do not cut so far back as to endanger the deep fascia of the perineum, and use the knife in the deep incisions with the cutting-edge uppermost. 5. Do not close the end of the inlying catheter, lest urine be forced into or through the wound, for want of patency in the instrument. 6. Avoid escape or displacement of the instrument. 7. If incisions are made far back, introduce a curved tube through the wound when the catheter is withdrawn. 8. Do not neglect dilatation during the progress of recovery.

(b) *Impermeable Stricture*.—This condition of stricture is very rare, if it ever exists. As Syme justly observes, any stricture through which urine can escape, will admit an instrument to be passed with care and patience. Then, of course, the operation may be performed as for permeable stricture. Otherwise, a catheter of full size, having been passed down to the stricture, and held there firmly by an assistant, perineal section is performed; the point of the instrument being the guide to, but not through, the stricture. Having clearly reached that point, the Surgeon endeavours to pass a small grooved director through, or partly through, the stricture; and on this instrument he at once divides, or successively pursues, the track of the contracted canal. When no director, however small, can be introduced, the urethral canal must be followed without any such guide, by dissection alone cautiously conducted. In either case, as soon as the continuity of the passage is restored, the catheter above is to be carried on into the bladder, and retained in the usual manner for a period of some days.

*Results of Perineal Section*.—The latter operation of external incision,—without an urethral guide, is of course hazardous and uncertain in its results. But external incision, as performed on a grooved staff, has

yielded excellent results,—in an appropriate condition of stricture, and when the operation has been properly performed. Among 219 cases of this operation, collected with scrupulous care by Sir H. Thompson, there was a mortality of between 6 and 7 per cent. Of this percentage, nearly two-thirds died of pyæmia, the remainder, one or two only excepted, from fever and suppression of urine. Such a mortality is not large, considering the extreme cases of stricture and broken constitutions, subjected to the operation.

The *pathological conditions* of stricture submitted to operation, will of course materially affect the proportionate result of apparently successful cases. Perineal section is appropriate for the condition—originally proposed—an almost impermeable stricture, and which is otherwise incurable by dilatation,—and this is always implied, when *properly* speaking of the operation and its results; but I have seen perineal section performed when, at the time of operation, a full-sized catheter had just before been passed, easily, into the bladder,—and the operation having been performed simply for extravasation of urine.

SPASMODIC STRICTURE.—This kind of stricture is due to the spasmodic action of the muscles surrounding the urethra, and is of a temporary character. It rarely occurs alone, but usually as a supervention on organic stricture, or in connexion with an inflamed state of the urethral canal. Spasmodic stricture may occur at any portion of the urethra, by contraction of the layer of involuntary muscular fibres which encircle it throughout its course; or the membranous portion of the urethra may be constricted by spasm of the compressor urethræ muscle, acting as a sphincter on this portion of the passage, and this is the usual seat of spasmodic stricture of the urethra.

The *symptoms* are those of obstruction to the passage of the stream of urine, but of temporary duration although perhaps oft-recurring. They thus differ from the same symptoms in organic or permanent stricture.

*Causes.*—Local and urethral conditions, or remote and constitutional conditions, may severally give rise to spasmodic stricture. The first class comprises, chiefly;—the presence of organic stricture; of inflammation from suppressed gonorrhœal discharge; irritation of the urethral mucous membrane from various states of the urine, especially a highly acid state, with various constitutional conditions, as gout; foreign matters ingested and expelled by the urine, as cantharides, turpentine, condiments, alcoholic drinks; and the voluntary retention of urine for too long a time. The second class of causes, comprises, chiefly:—rectal irritations; as hæmorrhoids, fissure, prolapsus, fistulæ, operations on the rectum, ascarides, and anal prurigo; derangements of the digestive organs, and of the cerebro-spinal system. The *social* circumstances under which the practitioner will commonly meet with spasmodic stricture are characteristic. As affecting the more affluent classes of society; the indulgence over-night of acid wines, punch, or stimulating food and condiments, at supper-parties or convivial meetings, may be followed next morning by an attack of spasmodic stricture, especially in persons of a gouty diathesis. The restraints of society with regard to the retention of urine, the outdoor amusements of hunting, steeple-chasing, or other rough riding across country, are also circumstances under which spasmodic stricture is liable to occur. Or the picture may be reversed; the combined effects of cold and exhaustion drives many a homeless wanderer to seek relief at an Hospital during the early hours of our winter mornings. The anxiety

and harass of business, the pressure of over study, or of writing against time in newspaper offices, &c., may subject the commercial and the literary classes of society to the penalty of an attack of urethral spasm.

*Treatment.*—The cause of spasm must be sought, and if possible removed. In an attack of spasmodic stricture, remedial measures must be directed to the relaxation of the muscular contraction. The most effectual antispasmodics are a warm bath, and a full dose of opium,—the tincture or Battley's sedative. I have used a drachm or more of the compound tincture of camphor with advantage. Chloroform inhaled, has sometimes afforded instant relief. Suppositories have not had much effect. This antispasmodic treatment is most successful when the stricture arises from exposure to cold. But, if the gouty diathesis prevails, or the circumstances of origin point to acidity of urine; then, alkalies and other appropriate remedies must be combined. Catheterism should be avoided as long as possible, the introduction of an instrument tending to provoke spasm; and when resorted to, the catheter used should be full-sized or at least one of the higher numbers.

**INFLAMMATORY STRICTURE.**—An inflamed or congested state of the urethral mucous membrane may occasion a species of temporary stricture. It is less an independent condition, than engrafted on a pre-existing organic stricture, or coincident with spasm.

The *symptoms* are somewhat peculiar. In addition to obstructed micturition, the penis is turgid and erectile, and the urethra bleeds freely on the introduction of even a moderate-sized catheter; there is intense scalding in passing urine, and the stream narrows rapidly during the act, ceasing abruptly before the bladder is emptied. The urine is, as it were, shot out at short intervals from the bladder, itself in an irritable state. Perineal heat, fulness, and tenderness, are complained of, when the inflammation extends far back. In all these respects, inflammatory stricture contrasts with that produced by spasm.

*Causes.*—Retrocedent gonorrhœa, or suppression of the discharge by exposure to cold or wet, or by an inconsiderate recourse to injections during the inflammatory stage. Indulgence in alcoholic liquors or a stimulating diet, will also contribute to the inflammatory or congested state of the urethra.

*Treatment* must be conducted on ordinary principles. This urethral condition resulting usually from suppressed gonorrhœa, it will subside on the reappearance of the discharge. Wrapping the penis in a poultice is a simple remedy which I have often found successful.

**TUMOURS IN THE URETHRA.**—Growths within the urethra, formerly known as “caruncles” or “carnosities” and supposed to be common, are extremely rare. Their nature, according to Sir H. Thompson's careful examination of recorded cases, seems to be of three kinds:—vascular granulations; polypoid formations peculiar to the prostatic part of the urethra; masses of tubercular and cancerous origin. Both the latter forms of deposit are rarely primary in the urethra, but secondary to disease of the kidney, bladder, or prostate; and they seldom appear until the primary disease is far advanced.

The local importance of any such urethral tumour is the degree of obstruction thus offered to the free passage of urine, as a cause of retention.

*Treatment.*—Urethral growths may be removed on the same principles as similar tumours in other parts;—by Excision, Ligature, Caustics, or

the Actual Caution. Excision can generally be accomplished by means of fine scissors, aided by dilatation of the urethra. In this way I have succeeded, especially as regards the female urethra, in removing vascular and erectile growths, which although not of large size were very troublesome. Ligature is difficult, painful, and tedious. Caustic applications, as nitric acid or potash, can scarcely be restricted in their action to the growth alone; and the actual cautery by means of the galvanic wire will be preferable.

**CALCULUS IN THE URETHRA.**—Urethral calculus is generally derived from the kidney and bladder, or from a fragment of stone becoming arrested in some part of the canal; but rarely, the calculus forms within the urethra, by deposit in the sacculus or dilatation behind a stricture. Here urine constantly collecting may give rise to concretion, or it forms around a particle of calculous matter as a nucleus.

The calculus is usually of the lithic acid variety; it more than occupies the calibre of the canal transversely, and assumes an elongated form; it may attain to a very large size. Several calculi are sometimes present; small, smooth, and faceted.

FIG. 458.

The *symptoms* are obvious; frequent and difficult micturition, bordering on retention; and the stone may be felt externally in the perineum or detected by introducing a sound, which may at once strike against the calculus, or grate roughly over it when imbedded in a dilated portion of the urethra. (Fig. 458.)

Rectal exploration with the finger is often serviceable. Care must be taken, in either case, to guard the canal on the vesical side, with the finger, lest the stone be pushed back or it might slip back into the bladder. Pain in the situation of the calculus is sometimes experienced, and especially if the stone be rough, and moveable in the act of micturition; but not unfrequently there is no such symptom, and the calculus is singularly quiescent and unsuspected.

Ulceration and abscess are liable to ensue, resulting in extravasation of urine, and urinary fistula.

**Treatment.**—Expulsion of the calculus may occur in the passage of a full stream of urine. Hence, the Surgeon sometimes avails himself of this natural mode of cure, by directing the patient to retain his water as long as possible, and then to compress the urethra with his finger in front of the calculus when he endeavours to micturate; the stream of urine coming out suddenly with a forcible gush, carries before it the stone. The removal of an urethral calculus must, however, generally be effected either by extraction or by incision. When situated in *front* of the scrotum, the calculus can often be extracted; by passing down the urethra a long, slender, urethral forceps (Fig. 459), aided by moderate dilatation; or failing thus to remove the stone, it should be pushed back into the

FIG. 459.

perineum, and thence removed by incision, any incision of the urethra in front of the scrotum generally resulting in a fistulous opening. A stone lodged in the navicular fossa near the meatus, may perhaps, be eased out by a slight incision of the orifice with a probe-pointed bistoury.

When the calculus is situated in the *perineal* portion of the urethra, or has been pushed back to that part; it should be removed by a clean median incision,—external urethrotomy, at the same time compressing the urethra firmly with the finger behind the stone, lest it accidentally recede into the bladder. If this happens, a long pair of slender forceps may be introduced and the stone extracted.

After the perineal incision, there is little risk of urinary extravasation, and less of fistula or of stricture resulting.

**RETENTION OF URINE.**—This term is understood to signify an inability, arising from various causes, to pass any urine, or only a very small quantity. It thus differs from the partial retention of urine in engorgement of the bladder with occasional overflow, and which is dependent on enlargement of the prostate. Moreover, the one is a recent or acute condition, the other an habitual or chronic condition.

The *symptoms* are not only an absence of micturition, or the escape of urine by drops after much straining and painful effort; but also, as the bladder becomes distended and rises above the pubes, there is dulness on percussion over that region, extending upwards at length perhaps to the umbilicus. This is accompanied with much distress and constitutional disturbance.

*Causes.*—Various causes may give rise to retention of urine, but they are all reducible to two classes:—that of *defective expulsive power*, in *paralysis* involving the abdominal muscles and bladder; and that of *obstruction* to the passage of urine; as dependent on *prostatic enlargement* from any cause,—inflammation, chronic hypertrophy, or tumour, of a sufficient size to block up the internal meatus of the urethra; *perineal abscess*, occasionally; *stricture of the urethra*, organic, spasmodic or inflammatory; *urethral tumours*, *calculi*, or other foreign bodies in the urethra, occasionally.

*Consequences.*—Unrelieved retention of urine leads generally to *rupture of the urethra*, and especially when the source of obstruction is in the urethra, the canal yielding behind that point, and this event being followed by extravasation of urine; rarely, *rupture of the bladder* occurs in consequence of retention.

*Treatment.*—Retention of urine must of course be regarded with reference to the removal of its cause; but the bladder admits of being entered, and the accumulated urine drawn off, in five different ways:—(1) by catheterism; (2) incision of the urethra through, or behind, the obstruction, usually in the perineum; (3) puncture of the bladder,—through the rectum, (4) above the pubes, or (5) through the symphysis pubis.

*Catheterism.*—This mode of gaining admission to the bladder will usually succeed; in conjunction with the appropriate treatment for any temporary spasmodic or inflammatory obstruction, which may have become engrafted on an organic stricture, from some excess or from exposure to wet and cold,—the circumstances under which retention generally arises. Accordingly, a small-sized catheter is selected, about number 4 or smaller, silver or gum-elastic; and the instrument introduced with due attention to gentleness, caution and patience. The stricture may often yield more readily than might have been anticipated when retention is present, owing

to the dilatation effected by the pressure of urine above; or on withdrawing the instrument from just the entrance of the stricture, the urine will often follow in a full stream. If the Surgeon fails in thus affording relief by catheterism; he should have recourse to relaxatives or local blood-letting, as the case may be. With spasmodic stricture; the patient should be placed in a warm hip bath, and opium given by the mouth, or in the form of enema or suppository, or chloroform administered; the latter agent being of great value in overcoming both voluntary and involuntary muscular resistance. With an inflammatory or congestive state of the urethral passage, as evinced by a turgid penis and tender perineum; local blood-letting from the latter region, by cupping or a dozen leeches, will often effectually subdue this occasion of resistance. After either kind of auxiliary treatment, the introduction of a catheter can generally be accomplished. Recourse to auxiliary measures may be deemed advisable *before* attempting to pass an instrument, and certainly this would be better than any risk of injuring the urethra by rough manipulation.

*Forcible catheterism*, or forcing the stricture as it is termed, will rarely be justifiable; and never in the sense of thrusting a catheter anyhow into the bladder. The forcible dilatation or rupture of an old indurated stricture, as by Holt's operation, is an occasional resource for the relief of retention.

*Incision of the urethra through, or behind, the stricture.*—The first named point of incision, through the stricture, is in fact perineal section; and the second may be performed in a precisely similar manner. The one has the advantage of relieving the stricture as well as the retention; the other leaves the stricture untouched, and it is performed without a guide in the urethra, by carefully deepened incisions so as to hit the passage; the finger having been introduced into the rectum to indicate the point in front of the prostate,—the membranous urethra. This procedure was recommended by Guthrie and Liston, though it has now generally given place to puncture of the bladder per rectum. Both these urethral modes of entering the bladder have the advantage of not directly opening the bladder; and, in relieving retention, they also release any extravasated urine, or matter which may have formed in the perineum.

*Puncture of the Bladder through the Rectum.*—Having emptied the bowel by an enema, the patient is brought to the edge of the bed and his legs held apart as for lithotomy. The Surgeon then introduces the left fore-finger, oiled, into the rectum, and feels for the posterior margin of the prostate; just beyond which point, fluctuation should be perceptible, especially on tapping the hypogastric region with the other hand. The long curved trocar and canula is then passed along the concavity of the finger, as a guide, to the same point, in the middle line

FIG. 460.

and pushed upwards into the bladder; transfixing the rectum and base of the bladder, in the *trigone* of the latter organ where it is uncovered by peritoneum. (Fig. 460.) This space is free from adjoining parts; the prostate in front, the reflection of the peritoneum behind, and the vesiculæ seminales are on each side. The trocar is now withdrawn, the bladder emptied, and the canula retained by means of a waist-bandage and tapes. In performing this simple operation, two additional practical points are worthy of notice; in passing the instrument along the finger, let the point of the trocar be withdrawn into the canula, to avoid wounding the bowel; and leave the canula in, but only just within the bladder, to prevent any irritation of the mucous membrane by the edged-end of this tube. It is allowed to remain for a few days, until urine flows by the natural channel, or until stricture of the urethra or other obstruction has been overcome.

The value of puncture by the rectum has been variously estimated. Mr. Cock, who has performed this operation in a large number of cases, is led to very favourable conclusions respecting it; that it is more easy of performance, and less dangerous in its results, than any mode of entering the bladder for the relief of retention. The objections made to the operation are—not so much the liability of perforating the peritoneum or seminal vesicles, both of which parts may with care in performing the operation be avoided—but the liability to urinary infiltration, pelvic inflammation and abscess between the rectum and bladder, and a persistent fistulous opening. In one singular case that Mr. Erichsen relates, rectal flatus became diffused through the cellular tissue of the pelvis and down the thighs and nates; an emphysematous condition from which the patient died.

Puncture through the rectum seems to be appropriate only when; with retention from stricture, there is no sign of abscess or extravasation in the perineum, the urethra is apparently not dilated behind the stricture, the prostate not much enlarged; and a catheter cannot be passed under chloroform, and with care and patience. These circumstances will considerably restrict the cases for having recourse to this operation.

*Puncture of the Bladder above the Pubes* is easily performed. A vertical incision in the middle line and just above the symphysis pubis, is made to the extent of about two inches, and carried down through the linea alba, so as just to admit the tip of the finger to reach the distended bladder. An assistant steadies this organ by even pressure with his hands against the abdominal wall, on either side; and a slightly curved trocar is entered downwards into the bladder (see Fig. 460), the urine drawn off, and the canula allowed to remain for a few days as may be necessary. It is secured by tapes and a T bandage.

This operation has been often practised, and strongly advocated by Mr. Paget of Leicester, and by some other Surgeons of eminence. But it is not generally resorted to. The objections are, some risk of urinary infiltration, or of a fistulous opening remaining. But there may be no alternative between supra-pubic puncture—and rectal puncture, or even the perineal section; when, with impassable stricture, the prostate is considerably enlarged. Rectal-puncture may be absolutely impracticable, from the impossibility of reaching with the finger behind the enlarged prostate.

*Puncture of the Bladder through the Symphysis Pubis.*—An ordinary hydrocele trocar of medium size is introduced, with or without a small

preliminary incision, about the centre of the symphysis from above downwards, and in a direction at about right angles to the vertical axis of the body. It is thrust onwards, somewhat obliquely downwards and backwards towards the sacrum, this direction being varied according to circumstances; a piece of flexible catheter is then passed through the canula and retained by a tape. Dr. J. M. Brander of Jersey, in 1825, first proposed this operation; and several successful cases have since occurred in his practice, and in the hands of other Surgeons.

**EXTRAVASATION OF URINE.**—This may take place from unrelieved retention of urine; and generally, the urethra is ruptured behind the seat of obstruction, the bladder very rarely.

*Rupture of the Urethra* occurring behind the seat of stricture, the point of rupture is almost invariably the membranous portion of the urethra and just in front of the triangular ligament. Here, the urethra being naturally weak, it is also dilated in the form of a sacculus or pouch, by the constant distending pressure of the urine, resisted by the strictured passage in front. Under this pressure, the weak and dilated urethra tends to yield; but the immediate cause of extravasation seems to be ulceration of the mucous membrane, either from urinary irritation, or as the result of an abscess forming close to this part of the urethra, externally, and which induces ulceration into the canal. The urine escaping from the urethra, or becoming extravasated, into the adjoining cellular tissue, gradually infiltrates this texture beneath the deep layer of the superficial fascia in the perineum; and the fluid following the boundaries of this fascia, it forms a bag, limited by the base of the triangular ligament below, and the rami of the pubes laterally; thence continuing upwards, the scrotum and penis become infiltrated, then the lower part of the abdomen and outwards to the line of Poupart's ligament; but there is no extension downwards on the thighs.

The *symptoms* of extravasation are remarkable:—the characteristically bounded swelling, and its increasing size, and extent; the scrotum and penis especially becoming enormously distended, the one perhaps to the size of a large cocoa-nut, the other to that of a Bologna sausage; gangrenous inflammation of the cellular texture soon occurs; the skin assumes a dusky red hue, purplish or black gangrenous spots appear, and frequently one such patch is seen on the dorsum of the penis. Ultimately sloughing of the skin and cellular texture of the scrotum, exposes the testicles bare and pendulous. The constitutional disturbance is that of low typhoidal depression; a rapid feeble pulse, dry brown or black tongue, and muttering delirium as death approaches.

*Treatment.*—The primary indication of treatment is to give an immediate, free and dependent outlet to the extravasated urine, with the fetid purulent fluid and sloughs of cellular texture which soon form. This indication, is, therefore, both preventive and remedial. Hence an incision or two should be made in the scrotum on either side of the middle line; exposing the cellular texture, and extending from the front to the back of the bag. Another incision may be made on the dorsum of the penis, and perhaps another over the pubes. A quantity of strong-smelling or ammoniacal urine trickles out, and continues to ooze for hours or days; at the same time, the peculiar appearance of the cellular texture,—its pearly-white colour and tension, or its opaque, sodden, and matted appearance, indicates the degree of urinary infiltration, or the supervention of sloughing. Tension having been thus relieved, a catheter can often be passed

through the stricture into the bladder. This should be done at once, and the instrument retained in the usual manner by means of a waist-band and tapes. The catheter is left *unplugged*, that the urine may drain away from the bladder, and as the instrument occupies the *calibre* of the urethral canal, both these provisions will prevent any further extravasation. By this arrangement also, the ruptured urethra heals over the instrument. A large poultice or warm fomentation, or an antiseptic application, is placed around the scrotum and over the whole extent of the extravasation. The relief afforded by the incisions is almost instantaneous, the patient often soon rallying from the previous state of nervous prostration and low fever. Stimulants, in the form of wine or brandy, with supporting nutriment, may now be given advantageously; and bark with chlorate of potash, or ammonia, will prove very beneficial. Opium also is a most valuable agent; in the early period to counteract the nervous excitement which not unfrequently accompanies prostration, and afterwards when excitement sometimes prevails, to subdue it.

The subsequent treatment of sloughing and granulation,—after a long and trying process of exhaustion and repair, must be conducted on ordinary principles.

*Rupture of the Bladder*—occurring as a very rare consequence of retention—is attended with extravasation of urine into the peritoneal cavity; or more commonly, below the line of the peritoneal reflection, into the pelvic cellular texture, whence it may secondarily get into the peritoneum by ulceration.

The *symptoms* are, sudden and acute abdominal pain, the patient usually feeling that something has given way; and there is overwhelming collapse. Dulness on percussion over the region of the bladder is now substituted by general abdominal fluctuation and distension, with total incapability to strain out a drop of urine. Maniacal delirium sometimes supervenes. Death ensues in a period varying from thirty-six hours to four or five days.

The indication of *treatment* would seem to be that, an outlet should be given to the urine by puncture of the abdomen. But no such cases are recorded; and any treatment has hitherto had no effect in averting the inevitably fatal issue.

**URINARY ABSCESS.**—Suppuration circumscribed by plastic matter, forming an abscess, is liable to occur close to the urethra in some part of its extent. It may arise from any source of urethral irritation; usually the collection of urine in the dilatation behind a stricture, or from urethritis, or simply from the irritation of the passage of instruments. The suppuration is apparently induced either by ulceration of the mucous membrane, allowing of slight urinary extravasation into the sub-urethral cellular texture, and which thus becomes a direct source of irritation; or, abscess may perhaps result from the influence merely of the irritation in the adjoining portion of the urethral canal. In the one condition, abscess, proceeding from the canal, may open externally; in the other condition, abscess forming outside the canal, may open into it, and externally. Urinary abscess is liable to form in various situations, in relation to the urethral tract; and it is thence designated, *perineal*, *scrotal*, *intra-pelvic*, and *ante-scrotal* or *penile*. This also represents the order of frequency in the situations of such abscess.

*Symptoms.*—A small, circumscribed, hard, and painful tumour is felt, in the neighbourhood of the urethra; which scarcely attains any consi-

derable size, unless in the perineum. It is not attended by much constitutional disturbance.

*Treatment.*—Early incision is absolutely necessary, to prevent further extravasation of urine, or the establishment of urinary fistula. A free, and often deep incision, in the middle line, will give instant relief to tension or afford exit to matter. The part should then be well poulticed.

URINARY FISTULÆ commonly result from urinary abscess, communicating with the urethra, and externally. The internal opening is usually in the membranous urethra,—just behind the common seat of stricture; the external opening is commonly perineal or scrotal; and the intervening parts are traversed by the fistulous passage, or passages in various and often devious routes. Sometimes, the fistula is ante-scrotal or penile; and here the communication with the internal or urethral opening is almost direct. Less frequently, the openings of urinary fistulæ are found in the groins, the upper part of the thighs, the adjacent part of the nates, or even above the pubic symphysis. In size, the fistulous passages differ considerably; some admitting only the finest probe, others readily the finger. In point of number also, they vary remarkably; penile fistulæ being usually single, whereas, scrotal and especially perineal fistulæ are often numerous. Fifty-two openings, Civiale found in one such case. The surrounding structures differ so much in their condition as almost to warrant the distinction of urinary fistulæ into two classes; the *simple* or healthy fistula, and the *indurated* fistula. In the latter condition, the fistulæ are sometimes connected with cavities secreting pus, and detaining in their interior some quantity of the urinary secretion. The surrounding parts share the induration; the scrotum and penis becoming enormously enlarged and brawny or almost cartilaginous. Another and more important distinction, which characterizes a class of urinary fistulæ, is that wherein the urethral opening results from actual *destruction* and *loss of substance*, by sloughing; in consequence of urinary extravasation, phagedænic ulceration, or mechanical injury. A portion of the floor of the urethra having been destroyed, and the tissues intervening between it and the external surface; the urethral mucous membrane of the upper aspect or roof of the canal, becomes visible from the outer orifice of the fistula. Such apertures may be found in similar situations to those of abscess-fistulæ; as perineal, scrotal, and ante-scrotal or penile fistulæ.

The *symptoms* of urinary fistula, having reference to the act of micturition, are characteristic of the existence of such fistula; and are tolerably distinctive as to its situation, size, and mode of origin.

In all urinary fistulæ, the urine escapes partly, at least, by the fistulous opening, or openings; in the latter condition, the urine spurting out perhaps as if it were issuing from the rose of a water-pot. This may be often seen in perineal and scrotal fistulæ, where numerous openings frequently co-exist. The situation of the internal opening is less correctly indicated, owing to the devious routes of the fistulous passages. But the seat of stricture will supply this information. According to the size of the fistulous communication, more or less urine will escape through the unnatural passages; and proportionately, less or more by the urethra. And the mode of micturition in this respect is tolerably diagnostic of fistula which results from destruction of a portion of the urethral canal; the whole or nearly the whole of the urine then passing by the artificial channel in a full stream.

*Treatment.*—When a stricture, followed by abscess, is the cause of the

fistula; the primary indication of treatment will be the removal of that condition. This may be done in the usual manner; by dilatation, internal urethrotomy occasionally, external urethrotomy more commonly,—and usually the perineal section, owing to the situation of the stricture. Having thus succeeded in enabling the urine to flow by the natural channel; the fistulous passages are set at rest, and they not unfrequently contract and close. Thus, both simple, and even indurated, urinary fistulæ, may be cured.

But old, *indurated* fistulæ, are indisposed to heal, although the original cause has been thus removed. Recourse must be had to additional treatment for this purpose. The measures remedial in chronic fistulæ generally, are here also appropriate, and may have to be tried in succession. They are chiefly; stimulating applications to the fistulous tract; compression; and incision along the course of the fistula to induce healing from the bottom. Of *stimulating applications*, various agents have been employed; in the form of injection by means of a fine syringe, as tincture of cantharides, solutions of nitrate of silver, sulphate of copper or of zinc. A probe coated with fused nitrate of silver, may be passed along the tract occasionally, and this will often succeed in causing contraction. The actual cautery is sometimes curative applied in the form of a red-hot wire, or the galvanic-wire cautery, which can be conveniently introduced along the tract before being heated by the current. *Compression*, by means of an india-rubber air-pad, applied to the perineum, has proved successful in some cases of perineal fistulæ. *Division* of the fistulæ along their course nearly to their origin in the urethra, can be accomplished as usual, with a grooved director and narrow blunt-pointed bistoury. Several passages may be thus thrown into one, and strips of lint should then be inserted to provoke granulation from the bottom of the tract.

During recourse to these measures for the cure of urinary fistulæ, any passage of urine along their course, must be prevented, by regularly using the catheter three or four times a day. The patient may be instructed how to do this for himself, at every call of nature.

Respecting the eligibility of these modes of treatment; in long, narrow, and tortuous fistulæ,—stimulation and compression seem to be the most appropriate; when the fistulæ are large and numerous, incision is more suitable,—the perineum and scrotum being sometimes quite riddled in all directions.

Larger-sized urethral openings, in consequence of actual *destruction* of some portion of the wall of the canal, require operative interference of a plastic character, to repair the loss of substance.

*Urethro-plastic operations* are designed to effect reparation in one of two ways; either by simple closure of the fistulous aperture, or by borrowing the surrounding integument to accomplish this object. These procedures are severally applicable according to the part of the canal where the opening exists.

Perineal fistula may admit of closure by simply paring the edges down to the urethra, and uniting them with quilled sutures, or by Boze-man's buttons.

Ante-scrotal or penile fistula is much more difficult to close, owing to the want of substance in the coverings of the urethra at this part of its extent, and the liability of the part to disturbance by erection of the organ or other motion. When the opening is *small*, Dieffenbach's mode of closing it may be applicable. It consists in first stimulating the edges,

by frequently touching the surrounding skin with the strong tincture of cantharides, the day before the operation; and then using the "lace suture." A sound is introduced into the urethra beyond the opening; the operator takes a small curved needle, sharp at the point but not at its sides, armed with a stout silk waxed thread, and by means of a needle-holder introduces it beneath the skin at about three lines from the border of the fistula. The needle is carried deeply, but not into the urethra, and made to emerge at another point; then dipped again, and so on by three or four stitches, carried round the opening, until it emerges at the point of entrance. The thread, thus embedded in the cellular texture around the fistula, is drawn by its two ends together, so as to close the opening; and then fastened by a knot. In three or four days, the ligature may be divided and drawn away. A *larger-sized* aperture will probably require some substitution of the surrounding skin; and this may be accomplished by Nélaton's operation, as follows:—The edges of the fistula having been pared, the skin around to the extent of about one inch must be dissected by passing a small narrow-bladed knife subcutaneously around the aperture; thus producing a detached area of integument, which is brought together over the opening and the edges united by a few points of fine suture. This procedure may sometimes be advantageously modified by making lateral incisions, and then passing across underneath the flap a slip of india-rubber, to prevent contact of the urine which would disturb the process of adhesion in the line of closure over the urethral opening.

During the course of reparation by any of these urethro-plastic operations, the urine must always be drawn off by a catheter, three or four times daily.

URINARY VAGINAL, AND UTERINE FISTULÆ.—Fistulous openings may be established; (1) between the urethra and vagina; (2) between the bladder and vagina; or (3) between the bladder and uterus. These communications result; from contusions or lacerations in parturition, the introduction of foreign bodies, the effects of calculous concretions in the bladder, or operations for their removal. Openings caused by the extension of cancerous ulceration are here omitted, as such fistulæ are quite incurable.

Much, and persevering attention has been given of late years to the Surgical treatment of the various forms of simple fistulæ; and results have been obtained in a large number of cases, sufficient to establish the operative cure of these distressing conditions as a finished achievement. We are chiefly indebted for this addition to Surgery, to the labours of Dieffenbach, Dr. Bozeman, Mr. Baker Brown, Dr. Marion Sims, Professor Simpson, Mr. Bryant, and Mr. Spencer Wells.

The principal features connected with the operations as more recently practised, and which have led to their increasing success, are thus enumerated by Mr. Jonathan Hutchinson. Speaking chiefly of vesical fistulæ; 1st the use of chloroform, which facilitates the difficult step of the dissection; 2nd the use of metal sutures instead of silk; 3rd the avoidance of the vesical mucous membrane, both in the dissection, and in the application of the sutures; and 4th increased attention to keeping the bladder empty afterwards. It may be added, that metallic or wire shields, adjusted over the line of union, were much relied on a few years since; but they are now generally discarded in favour of sutures alone.

*Vesico-vaginal fistula*, may be taken as the type of the three urinary fistulæ, relating to the vagina and uterus. The requisite operation con-

sists, in completely paring the edges of the vaginal aspect of the fistula, and then uniting them by suture. But many particulars should be observed, as tending materially to the success of this procedure; and they are tersely stated in the following summary by Hutchinson, which I can endorse by my own experience:—The instruments used are small tenotomy-like knives, forceps, needles, and fine silver-wire. Instruments for carrying the wire have also been devised; as Startin's tubular needle. The patient should be in her best state of health, and the bowels have been well cleared out. Chloroform having been given, the woman is placed either on her side with the knees well drawn up, or in the usual lithotomy position. The parts being thoroughly exposed by a duck-bill speculum, and the nates being held widely apart by an assistant; the operator proceeds to drag the opening as low down as possible, with a view to facilitate the paring of the edges. This may be accomplished either by hooks, blunt or sharp; by means of a metal suture; or by the introduction of a flexible sound through the urethra, which is brought out again through the fistula, and then bent backwards. This latter plan furnishes the Surgeon with a most efficient hook, and one which cannot easily slip. In paring the edges, it is necessary thoroughly to denude every part; for if the smallest portion of mucous membrane be left, it may prevent union. None of the mucous membrane of the bladder must be removed. The wound should present a bevelled oblique line, slanting from a large vaginal opening to a smaller vesical one. The denudation being complete and free, sutures are next to be introduced. These should be passed obliquely from at least a third of an inch outside the edge of the incision. They must not include the mucous membrane of the bladder. The tightening and tying of wire sutures is easily accomplished by the fingers. Care must be taken not to pull them too tight, so as to invert the edge of the vaginal mucous membrane.

*After-treatment* is simple:—The small double-curved silver catheter, invented by Dr. Sims, or an ordinary gum-elastic one, should be passed and retained unplugged; that the urine shall constantly drain out of the bladder. This should be constantly watched; and the instrument cleansed and then re-introduced twice a day. The patient must lie on her side with the knees drawn up; and her general health be well sustained. It is of the utmost consequence to prevent the action of the bowels for at least a week; and this may be accomplished by administering a full dose of opium soon after the operation, and maintaining its influence subsequently by smaller doses. Dr. Sims lays much stress on this point, as an element of success. The removal of the sutures prematurely is a greater evil than their unnecessary continuance; they should certainly not be withdrawn before the ninth or tenth day, and then with great caution.

*Urethro-vaginal fistula* is more easily closed by a similar procedure; but union takes place less readily, owing to the unavoidable pressure of the catheter on the line of union.

*Vesico-Uterine fistula*, is that condition wherein the fistulous communication exists between the bladder and cervix uteri. Certain modifications in the plan of operation will be required. It might become desirable to obliterate the upper part of the vagina, in order to connect the uterus with the bladder; thus allowing the menstrual fluid to pass through this organ, but preventing incontinence of urine.

These operative procedures may have to be repeated a second, or third time, and even several times, in the same case; partial closure only being

effected in the first instance, and afterwards more and more completely. Such temporary failure, however, will not weary the perseverance of the true Surgeon, nor the endurance of the patient,—who is too glad to get rid even by degrees, of a most troublesome, offensive, and socially distressing urinary leakage. But, it not unfrequently happens that a pin-hole opening, only, remains, defying any plastic procedure. In common with many other Surgeons, I have had to contend with this difficult residue of the operation. No means of closing the aperture will, I believe, prove effectual except the introduction of a red-hot wire, or better,—the galvanic-wire cautery.

## CHAPTER LXI.

### INJURIES AND DISEASES OF THE PENIS.

THIS organ is liable to Injuries and Diseases in common with other parts of the body, presenting, however, peculiar features of importance; and to certain Malformations or Congenital Defects which are necessarily peculiar to it.

*INJURIES.*—*Wounds*, and *Laceration*, of the Penis, present two important characters; copious hæmorrhage, and possibly, implication of the urethra. These lesions may be produced by instruments,—whether sharp-cutting, penetrating or lacerating, or by external violence, as gunshot injury; and they may be accidental, or sometimes vindictively inflicted, or even self-inflicted. But, the tendency to reparation is remarkable, especially in the integumental portion of the organ.

*Hæmorrhage.*—The erectile structure of the penis is not unfrequently the source of hæmorrhage; the blood issuing either from the corpora cavernosa, the corpus spongiosum, or from both; and in the form of a free, persistent dripping or oozing. The dorsal artery, or the artery of the corpus cavernosum, may, however, be the source; the blood issuing in the usual manner, as a jetting arterial stream. In extensive wounds of the penis, the blood proceeds both from the erectile structures and from the arterial trunks.

The *treatment* will vary accordingly. Oozing hæmorrhage may be arrested by cold or astringent applications, and pressure. A large catheter should be passed into the bladder, as a means of counter-support, and compression effected by a finger-bandage or circular strips of adhesive plaster. Compression with a pad of lint, thus retained, is sometimes sufficient, without the resistance afforded by a catheter. Arterial hæmorrhage must be managed by ligature; or perhaps torsion, when the vessel is free and can be well twisted with the forceps.

*Wound of the Urethra.*—This lesion may occur as part of a penile wound, or independently,—the urethra alone being cut or penetrated. And the wound may be partial or complete division of the urethra.

The *signs* are; the escape of blood from the meatus, or in micturition,—bloody urine and escape of urine from the urethral wound. In the ante-scrotal portion of the penis, the wound is easily discovered on examination.

*Treatment* consists, in at once passing a gum-elastic catheter through the external meatus into the bladder, and retaining the instrument; the

edges of the wound can then be brought together over the instrument, by fine strips of plaster or a point or two of suture.

*Laceration* of the urethra, is specially apt to occur in connexion with fracture of the pubic rami; or, from external violence; as a kick in the perineum, or a fall astride a girder or the edge of a plank of wood. The membranous urethra is here the seat of injury; and the laceration may be partial or complete,—the urethra being torn partly or entirely across. There is also more or less perineal ecchymosis or bruising.

Certain *signs* are distinctive of laceration. Urethral hæmorrhage or bloody urine occur as from wound; but the effort of micturition is accompanied with a deep burning pain, and symptoms of urinary extravasation, commencing in the perineum, rapidly ensue. If laceration be complete, there is inability to pass urine, and extravasation proceeds with greater rapidity. This condition may terminate in urinary fistula.

*Treatment* is essentially the same as in wound of the urethra. A catheter should be at once passed, to allow of urethral reparation, and, in the case of laceration, to prevent the extravasation of urine which cannot here escape by an external wound. With *complete* laceration of the urethra, it may be very difficult or impossible to pass a catheter. Having, therefore, introduced the instrument as far as it will go; a free incision should be made in the middle line upon the point of the catheter, which can then probably be passed onwards into the bladder. Or at least an outlet is thus provided for the urine. If, with this precaution, retention ensues, puncture of the bladder through the rectum may be justifiably resorted to.

*Extravasation of urine*, or perhaps urinary fistula, as the result of urethral laceration, must be treated as already explained with reference to these conditions.

**DISEASES.**—**BALANITIS.**—Inflammation of the thin mucous membrane of the prepuce and glans penis, is attended with some redness and smarting, and a profuse, thin, opalescent, muco-purulent discharge, with some infiltration of the prepuce bordering on phymosis. Excoriation is apt to occur. When the mucous membrane of the glans is specially affected, the inflammation is known as *Posthitis*. The prepuce is not unfrequently long and redundant, a condition which seems to predispose to Balanitis.

FIG. 461.

This inflammatory affection is usually the result of local irritation; from gonorrhœal discharge frequently, and hence named “external” gonorrhœa, or simply from want of cleanliness; but it also arises in young and delicate boys, from disordered health, and during hot weather.

The *treatment* is chiefly topical; a slightly astringent wash, as lead lotion or lime water, or slight pencilling with nitrate of silver, especially in the groove around the corona glandis. Saline, cooling medicine may also sometimes be given with advantage.

*Chronic Balanitis*—unattended with much redness and smarting—often induces a fleshy, rough or granular thickening of the preputial mucous membrane, and the discharge is still abundant. In this state, the membrane may be dusted with a mixed powder of calomel and

calced magnesia. When conjoined with phymosis, astringent injections must be used beneath the prepuce, which cannot then be uncovered.

**PHYMOSIS.**—By this term is meant a contracted state of the orifice of the prepuce or fore-skin, whereby the glans cannot be uncovered completely, if at all; the orifice being reduced to even a pin-hole opening. (Fig. 461.) This condition of the prepuce may be congenital, or acquired; and these two modes of origin sometimes co-exist.

*Congenital* phymosis, a not uncommon defect, is associated usually with an elongated and redundant state of the preputial skin, so as to project beyond the glans; but the mucous membrane is deficient, and thus prevents retraction. Adhesions sometimes exist between the opposed surfaces of this undeveloped membrane and the glans; and the glans itself is small, owing apparently to the restriction offered by the prepuce to its development.

A source of inconvenience only at first, phymosis gives rise eventually to symptoms of vesical irritability, incontinence, and even to retention of urine; or often to symptoms simulating stone in the bladder. By the accumulation of sebaceous preputial secretion, irritation and inflammation of the part, or balanitis is apt to arise; and in after-life, sexual intercourse is rendered abortive by the contracted prepuce retaining the emitted semen. Impotency might then be suspected. In the event of gonorrhœal or syphilitic infection, the preputial condition more or less conceals the nature of the case, and interferes with the local treatment.

*Acquired* phymosis, is the result of repeated balanitis and thickening of the prepuce, or of chancres with induration, or their cicatrization and contraction,—especially when seated near the orifice of the prepuce.

*Treatment.*—The cause and the degree of phymosis will indicate whether the remedial measures should be operative, or not. In *acquired* phymosis; an acutely inflamed state of the prepuce, or an unhealthy sore, forbids operative interference, lest the wound should become unhealthy. Preputial injections may be used, and when the causative condition has been subdued, the phymosis will probably gradually disappear. Otherwise recourse must be had to operation. But if the contracted prepuce conceals the nature of a sore; or, if this having a destructive character, as a phagedænic or sloughing ulcer, the requisite applications cannot be made; then an operation is at once necessary to expose the sore for its treatment, though not to relieve the phymosis. In *congenital* phymosis, an operation may always be performed, for the sake of convenience and cleanliness; unless the prepuce can be retracted with tolerable facility for either purpose. This, however, is usually the tightest form of phymosis, and where the prepuce is also redundant.

The operations for phymosis are of two kinds; the contracted prepuce may be slit-up, or circumcision may be performed. Both operations are sometimes requisite.

*Slitting-up of the Prepuce.*—A grooved director is introduced between the prepuce and glans, and moved to the front so as to know that it is not in the urethra; a narrow, curved, sharp-pointed bistoury is then passed along the groove and thrust through the prepuce, dividing it as the knife is withdrawn outwards. The mucous membrane and the skin should be severed to an equal extent, but the incision need not be more than half an inch in length, the contraction being at the orifice of the prepuce. Two or three points of suture will be necessary to bring the

mucous membrane and skin together, in each half of the prepuce; and thus promote union by adhesion. If this be not done, the skin and membrane become separated by considerable swelling after the operation, and heal by granulation.—a slower process, and which leaves a thickened margin to either flap of the prepuce. I am accustomed to modify this simple operation to a procedure yet more simple; I divide only the mucous membrane, and retract the prepuce as the knife is withdrawn; thereby unsheathing the glans to the requisite extent for its complete release. A blunt-pointed bistoury, or a concealed knife, may be used; the latter instrument being sufficient for the operation without a director. Of course, no sutures are required.

*Circumcision.*—The prepuce must be drawn well forwards, until that portion which corresponds to the back of the glans is brought in front of it; the projecting prepuce is then seized immediately in front of the glans with a pair of narrow-bladed forceps, and held by an assistant; when the free portion of prepuce,—already placed on the stretch—is severed just in front of the forceps by one stroke of a bistoury. On removing the forceps, the mucous membrane will be seen embracing the glans, and this must be snipped-up with a pair of blunt-pointed scissors, sufficiently to uncover the glans; and the frænum also snipped across if necessary. Any small arteries, on either side, and one or two near the frænum, must be secured by ligature or torsion; although bleeding slightly at the time, these vessels are apt to be the source of profuse hæmorrhage afterwards, even to the amount of three or four pints of blood. A few points of suture,—five or six, should then be inserted to unite the mucous and cutaneous margins around the circular incision.

In congenital phymosis sometimes, adhesions between the prepuce and glans require to be dissected up; or a quantity of white epithelial matter may have accumulated as a cake around the glans, and this must be gently scraped off.

Of the two operations,—slitting, and circumcision, of the prepuce; the latter procedure is more generally applicable, as giving the cleanest result, and it is absolutely necessary when the prepuce is in a diseased state.

FIG. 462.

*PARAPHIMOSIS.*—In this—the opposite condition to phymosis—the prepuce is in a forcibly retracted state behind the corona glandis, whereby the glans cannot be covered. (Fig. 462.) The constricting preputial orifice soon becomes the source of strangulation; resulting in swelling of the prepuce, which encloses and buries the seat of stricture in a deep furrow, with a roll or collar of the swollen prepuce in front and behind; congestion and swelling of the glans are superadded; and

thus the reduction is rendered proportionately difficult or impossible. Most severe pain attends this state, increasing to torture; and ulceration and extensive sloughing are apt to ensue.

Paraphimosis occurs most commonly in boys; or in adults, who having naturally a narrow preputial orifice,—or tendency to phymosis, happen to have allowed the prepuce to remain drawn back for a while. A diseased and indurated state of the prepuce, when retracted, will also

tend to induce constriction; and paraphymosis not unfrequently arises in this way during primary syphilis.

*Treatment.*—*Reduction* should be effected without delay. Any cold or astringent applications are of little avail, the source of constriction and strangulation still remaining. Chloroform may sometimes be administered, as the reduction by manipulative compression is necessarily painful, and of some duration. Then the Surgeon takes the body of the penis between his fore-fingers, just behind the swollen prepuce; he compresses and pushes back the glans with his thumbs, at the same time drawing the prepuce forwards, which slowly rolls over the glans as this disappears. There will still be a tendency to retraction, so that a little continued compression of the whole end of the organ, for a minute or two, may be advisable. In ninety-nine cases out of a hundred, this method of treatment will prove successful.

When reduction cannot be effected by this procedure, after fair trial, the stricture must be *divided*. This is done by separating the two swollen folds of the prepuce to reach the circular constriction, in the furrow between them; and then dividing it with the point of a narrow bistoury on each side of the middle line, thus avoiding the dorsal vessels of the penis. A slight incision, almost a touch with the knife, will be sufficient to enable the prepuce to be drawn forward in the manner just described. It may be requisite to make a few punctures in the swollen preputial folds to evacuate serous fluid, before reduction can be accomplished. And perhaps also, the effusion having become partly consolidated, the prepuce cannot be drawn forwards; although the stricture has been divided. But, in a few days, the swelling subsides by absorption, and then reduction becomes easy. The *period* after paraphymosis when division of the stricture becomes necessary, is, I should say, usually about thirty-six hours; and later than that, the swelling may have to be diminished by the additional aid of puncture, or by absorption.

*Gangrene.*—Inflammation and œdema of the prepuce are very liable to occur, but gangrene seldom, unless in consequence of a chancre having assumed a sloughing character or a state of sloughing phagedæna. Nevertheless, gangrene of the penis has been known to ensue in typhus fever and in paraplegia. A case of spontaneous gangrene occurred in a patient under the care of Mr. Partridge, in King's College Hospital; and I have known a gangrenous patch to form, in a patient whom I attended for orchitis which rapidly proceeded to sloughing.

*Hypertrophy of the Prepuce.*—As the result of chronic inflammation, a solid œdema of the prepuce may subside; but an hypertrophied condition or a kind of elephantoid growth of the prepuce may form, necessitating excision. In one such case, which Vidal relates, the organ had attained to an enormous size; as large as a thigh and reaching to below the knees. Yet this monstrous growth was successfully excised.

*Warts.*—The mucous membrane of the prepuce and glans is liable to be the seat of warty growths, as the result of long continued irritation from gonorrhœal discharge or that of a syphilitic sore. The ichorous matter accumulating under the prepuce gives rise to these growths, especially in the furrow around the corona glandis. Cleanliness is, therefore, the best preventive.

Treatment is removal of the growths; either by snipping them off with curved scissors, or destroying them by dusting the surface with a powder consisting of equal parts of *savine* and copper.

CANCER OF THE PENIS occurs in two forms; Scirrhus, and Epithelial

cancer. The characters of these diseases present nothing peculiar. *Scirrhus* commences as a hard tubercle in the groove under the glans, and thence infiltrates the body of the organ. Its production seems to be predisposed by congenital phymosis. Thus, of 12 patients with this form of cancer, who came under Hey's observation, 9 had congenital phymosis. Conversely, the Jews, who are circumcised, are, Travers states, seldom subject to the disease. *Epithelial Cancer*, is, Prof. or Humphry believes, the only form of cancer of the penis. It commences usually on the glans, as a firm, warty elevation, having a broad base. At first painless, and covered with a cuticular crust; this being shed or rubbed off, the growth becomes painful, bleeds a little, and soon ulcerates, discharging a thin, fetid sanguineous fluid. It spreads, destroying the glans, opening the urethra, and involving the prepuce. The inguinal glands become affected, but not distant organs. Occasionally, the prepuce is the seat of this form of cancer. Phymosis here also seems to be a predisposing condition; and the prepuce may be ulcerated through, disclosing the cancerous growth.

*Diagnosis.*—In the early stage of cancer, there may be some difficulty in distinguishing between a cancerous wart, and a common wart, or chancreous induration which has not ulcerated or has cicatrized. But the ulcerative tendency of cancer, and the character of the discharge, with the slow steady progress of the disease; are diagnostic. The somewhat advanced period of life, and the negative effect of treatment, will also corroborate the nature of the disease.

*Treatment.*—The only treatment is extirpation; either by circumcision, or by amputation of the organ.

*Circumcision* is appropriate only when the disease is strictly limited to the prepuce; a comparatively rare condition, whether as regards the origin of cancer of the penis, or the stage when this affection usually comes under surgical treatment.

*Amputation of the Penis.*—This is a very simple operation, yet certain particulars must be observed to ensure its satisfactory performance. Amputation may be effected by the knife, or the *écraseur*; the former instrument being generally preferable. The operation should always be performed near the root of the penis, in order to completely remove the disease. An assistant holds that part of the organ firmly between the thumb and finger, to prevent the liability of its slipping back under the pubes; and the Surgeon laying hold of the penis draws the integument slightly forward, and then severs the body of the organ near its root by one sweep of the knife from above downwards. If too much integument be drawn over the stump, it may overlay the urethral orifice; if too little, an inconvenient puckering ensues. Bleeding vessels are then to be secured; usually, five arteries require ligature,—the two dorsal arteries, the artery of the corpus cavernosum on each side, and one in the septum. The oozing surface of the corpora cavernosa will spontaneously cease to bleed, or hæmorrhage thence proceeding may be restrained by a compress, secured by a T bandage. Granulation and cicatrization close the wound, the skin becoming puckered around the urethral orifice. During and after this process of healing, this orifice has a tendency to contract, resulting in stricture of a most troublesome or even fatal character. To prevent any such result, a catheter should be introduced and kept in the bladder; the silver female catheter, or a gum-elastic one, may be used now that the urethral passage is so much shortened. When an instru-

ment is not easily borne, Mr. Teale's little addition to the operation will be convenient; a catheter is introduced, and the urethra and adjoining skin are slit up with a bistoury to the extent of about two-thirds of an inch. A single suture is then placed on each side of the slit, uniting the skin and mucous membrane. Perfect patency is thus given to the orifice, which has a long, oval form; and after cicatrization has finished, there remains a free opening into the urethral canal, and no mechanical aid will be required. This procedure is applicable also when contraction has occurred from cicatrization after amputation; thereby sparing much trouble and pain in endeavouring to effect dilatation. I have accomplished the same result, by simply inclining the bistoury forwards, in performing the amputation; so as to make an oblique, oval aperture of the urethral termination.

After amputation of the penis, the stream of urine is projected downwards between the legs; and this inconvenience may be avoided, as Paré suggested, by wearing a short funnel, adapted to the pubes over the stump, whereby the urine is carried away from the person.

The results of amputation of this organ for cancer, have been tolerably successful; especially as regards the epithelial form of the disease. In several instances, no recurrence has taken place, even for years; six, eight, ten, or twenty. Recurrence may, however, ensue; either in the stump, or in the inguinal glands. The latter may admit of extirpation.

Tumours, of a non-malignant nature, occasionally form in the penis. Thus, *fibro-plastic* growth in the prepuce has been known to occur, invading the corpus cavernosum; and *naevus* under the prepuce.

MALFORMATIONS.—(1) Deficiency of a portion of the urethra, laying open the canal from the external meatus, is a not uncommon malformation. It is a congenital condition by arrest of development.

*Hypospadias*, the most frequent form, is that condition wherein the under part or floor of the urethra is wanting; to the extent usually of the glans, or occasionally as far back as the root of the penis. Through the under fissure thus presented, the urine is passed somewhat inconveniently, and the semen is ejected in an unsatisfactory manner during sexual intercourse. When the fissure extends some way back, it may be impracticable to eject the semen into the vagina.

*Epispadias* signifies the opposite condition; that wherein the upper part or roof of the urethra is wanting, to a variable extent from the meatus, together with a corresponding portion of the glans and of the mesial junction of the corpora cavernosa. (Fig. 463.) This upper-fissure is perhaps more patent than an under-fissure; but epispadias is usually less extensive, unless in connexion with extroversion of the bladder, and it is certainly a much less common form of urethral deficiency. In a slight case, the Surgeon may well assure an anxious parent, that the boy will probably make as good a man as the father.

(2) *Absence of the Urethra* is occasionally met with, as in extroversion of the bladder; or the canal may be obliterated in a *portion* of its extent, or occluded merely by a membranous diaphragm, generally near the vesical orifice; or there may be a second meatus,—a variety of *hypospadias*, usually about an inch behind the normal one.

FIG. 463.

*Treatment.*—As a rule, it will be best to leave these urethral malformations alone; any such defect probably not having much functional importance, and being little improved by any operative procedure. When, however, the urethral deficiency exists to an extent which practically renders the person impotent; the hypospadias, or the epispadias, may perhaps be remedied by a plastic operation. The edges of the opened portion of urethra should be pared, and brought together by suture, over a catheter. Narrowing of the urethra may be dealt with by dilatation; and a membranous diaphragm perforated by a trocar, when its existence has been clearly ascertained.

## CHAPTER LXII.

### DISEASES OF THE SCROTUM, TESTIS, AND CORD.

**DISEASES OF THE SCROTUM.**—**INFLAMMATORY ŒDEMA** of the scrotal integument, is an affection of an erysipelatous character; and, owing to the loose structure of the sub-cellular tissue, it is attended with great effusion and swelling, with a marked tendency also to rapid sloughing. The skin becoming involved, the testicles and cords are soon exposed; and these organs may even hang pendulous entirely bereft of integument.

This affection is liable to occur in enfeebled persons, from any slight local cause of irritation; as a small wound, crack or abrasion; a boil or small abscess in or near the scrotum. Apart from the predisposing constitutional condition, sloughing of the scrotum rarely ensues. Thus, the scrotum is very seldom the seat of mortification from frost-bite; although such cases have been seen by Sir A. Cooper and Mr. Curling.

*Treatment* consists in elevation of the scrotum, with fomentations; and early, free incisions, on either side of the raphé, down to the most dependent parts of the swelling. Tension is thus relieved, and the tendency to sloughing. In the event of this issue, granulation and cicatrization proceed apace even after the most extensive exposure. Constitutional treatment must be conducted on ordinary principles, for sustaining the patient's strength during the consecutive processes of destruction and reparation.

*Anasarca* of the scrotum, in old, weak persons; should be met by puncture, rather than by incision.

*Œdema of the scrotum in new-born infants*, often occurs in consequence of some slight irritation of the skin. It subsides usually under careful attention to keep the part dry and powdered. Death, however, may ensue; a result which Professor Humphry witnessed in one case, and of which he cites two such cases.

**HYPERTROPHY OR ELEPHANTIASIS** of the scrotum, rarely occurs in this country, but is very common in tropical climates; especially China, India,—East and West, Egypt, and South America. It consists of a thickening of the scrotal integument, with infiltration of serum or oily matter; the latter being sometimes so abundant as to give to the whole the character of an oleaginous mass. The cremaster has been found thickened, and the spermatic cords elongated; but the testes are usually healthy. Hydrocele occasionally co-exists.

*Causes.*—A low chronic inflammation would seem to be the origin of

this disease; and it commences, either at some one point, thence spreading gradually over the scrotum; or as a tumefaction of the whole bag. There may be some locally exciting cause, as a fistulous tract; more frequently no source of irritation can be traced.

The part may remain smooth, or become tuberculated and corrugated; in either case, it has little or no tendency to ulcerate, unless in consequence of abrasion. Slowly increasing, without pain, the scrotal hypertrophy often attains an enormous bulk (Fig. 464), and weighs 50, 100, or even 150 lbs.; ultimately proving fatal by its distressing weight, or perhaps by the supervention of ulceration and incessant discharge. Ichthyosis not unfrequently co-exists in other parts of the body. Cases of Elephantiasis of the scrotum have been recorded by Clot-Bey, Mr. Liston, Sir W. Ferguson, Mr. Isaacson, Mr. Brett, Mr. Haynes Walton, Mr. Wiblin of Southampton; and as occurring in other parts of Europe, by Delpech, Larrey, Delusas, Auvert, and Nöggel.

FIG. 464.

*Treatment.*—In the early stage of this disease, it may perhaps be arrested by pressure and other means of allaying chronic inflammation of the skin. Such treatment failing to take effect, recourse must be had to the operation of excision, without delay.

*Excision.*—When the tumour is of moderate size, the testes and penis may be dissected out and saved; the hæmorrhage not proceeding to a dangerous extent. When the tumour has attained to a large size,—40 lbs. and upwards, it must be excised *en masse*, including the genital organs; the hæmorrhage of a partial excision would be so profuse as to be fatal during the operation; and even with the rapidity of complete excision, patients have sunk from loss of blood. In Mr. Walton's case, the scrotum was first tied in small segments close to the trunk, and the mass removed below the ligatures; then as each strangulated part was liberated, the vessels were secured. The scrotum weighed eight or nine pounds, and the patient recovered.

The general results of excision in this disease are shown by 161 cases wherein Mr. Esdaile operated, with the loss of only five per cent.

Tumours of the scrotum are rare. *Fibrous* tumour has, however, been known to occur in several instances, collected by Mr. Curling. It originates in the areolar tissue, is painless, and grows slowly; attaining sometimes to the enormous size of 20 or 30 lbs., and upwards. This species of scrotal tumour occasionally undergoes calcification; and some have been of the recurrent fibroid variety. The ordinary fibrous growth

has been removed successfully, even when of the largest size. *Fatty* tumour has been less frequently met with; and *Cystic* tumour is quite rare. Professor Humphry has met with only two recorded cases. Both the latter kinds of tumour have proved very difficult of diagnosis. Large *calculi* have every now and then been known to find their way from the bladder into the scrotum; thence escaping by ulceration or being excised.

*Cancer* of the scrotum is generally of the *epithelial* kind, and this occurs usually in chimney-sweeps. Hence the disease has been named *Chimney-sweeper's cancer* or *soot-cancer*. It appears to arise from the constant irritation by soot lodging in the folds of the scrotum, and is a common affection. Commencing usually as a flattened soft tubercle or wart of a leaden hue, and situated usually near the lower and fore part of the scrotum; this little lump slowly spreads, becomes indurated and covered with a crust or by a thick horny concretion. Subsequently ulcerating, an uneven open surface is exposed; having a sinuous edge with a hard tuberculated border and an indurated base, discharging a thin bloody fluid. Ultimately, the whole scrotum is destroyed, exposing the testicles, which are usually spared; and the inguinal glands become indurated. Death ensues from constant pain and continued discharge. The disease is then found to be a nearly local affection, not invading the lumbar glands or the abdominal viscera.

*Treatment*.—Free excision affords the only hope of cure, and this in proportion to the limitation of the disease. When it returns, the operation may be repeated; and again and again, even to the removal of the whole scrotum and testes, provided such free excision can remove the whole of the disease. Induration of the inguinal glands is no positive bar to the operation; for slight induration may afterwards subside or remain quiescent; while with greater induration and enlargement, these glands can perhaps be dissected out as part of the disease and operation of excision.

#### DISEASES OF THE TESTIS AND CORD.

Associated with the Testis and the Scrotum, the *TUNICA VAGINALIS* intervening between the two, may be the seat of certain diseased conditions; *Hydrocele*, and *Hæmatocele*, in their ordinary forms, as signifying either an accumulation of serous fluid, or an effusion of blood, within this serous sac. The spermatic veins are liable to undergo varicose enlargement, forming *Varicocele*.

Diseases of the *TESTIS* and *CORD* specially comprise five generic conditions;—(1) *Inflammation* or *Orchitis* and *Epididymitis*; (2) *Chronic Enlargement*—*Syphilitic*, and *Scrofulous*; (3) *Tumours*,—Fibrous, Cartilaginous, Cystic, Cancer; (4) *Atrophy* of the Testis; (5) *Functional Disorders*—Impotency, Spermatorrhœa, Neuralgia; *Congenital Malposition* of the Testis.

*HYDROCELE*.—In the widest acceptance of the term, Hydrocele signifies an accumulation of serous fluid, in connexion with the Testis or Spermatic Cord.

Ordinarily, the fluid is collected in the tunica vaginalis, enveloping the testis; sometimes, in a cyst or cysts, variously situated relatively either to the testis, or, in the course of the spermatic cord. Hence, Hydroceles may be divided into that of the *Tunica Vaginalis Testis*; and the *Encysted* forms, as relating either to the Testis or to the Cord.

An accumulation of serous fluid in the tunica vaginalis may occur in two conditions of the sac;—either, when the vaginal process of peritoneum has become obliterated, whereby the fluid is contained in a distinct sac,—constituting the *common* form of Hydrocele; or, when that tubular prolongation of peritoneum remains unobliterated, so that the fluid is contained in a sac which communicates with the general peritoneal cavity,—constituting *Congenital Hydrocele*.

*Hydrocele of the Tunica Vaginalis*.—The serous fluid is accumulated in a distinct sac, enveloping the testis; and this organ, somewhat enlarged, is usually situated at the lower and back part of the sac. Sometimes, the testis is flattened and spread out by constant pressure of the fluid; and the epididymis is then elongated, obliterating the pouch which naturally exists between the testis and epididymis. Or, the testicle may be separated from the back part of the sac by an increase of this pouch, which forms a second sac communicating with the general sac of the tunica vaginalis, between the testis and epididymis. Lastly, the testis may, occasionally, project into, and transversely across the hydroceleic cavity; forming a septum whereby the sac is divided into two compartments. The position of the testis is sometimes changed to the lower and fore-part of the sac, or it may lie wholly in front. The serous fluid is simply the natural secretion of the tunica vaginalis, or slightly modified by inflammation. Clear, and of a pale straw colour; this fluid may acquire a dark brownish or chocolate hue, in an old hydrocele, or rarely it has a white milky colour; in both cases becoming less transparent or opaque. In its composition, the fluid is albuminous, alkaline and saline; but there may be associated; fibrine in variable proportion, as indicated by spontaneous coagulation; or, red corpuscles of the blood, in a disintegrated state, when the fluid is dark coloured, with perhaps also flakes of cholesterine; or, products of inflammation occasionally, as flakes of lymph. In point of quantity, the fluid of hydrocele varies from six to twelve or twenty ounces, averaging less than a fluid pint; but it may have accumulated to double or treble that amount. The largest quantity I have ever tapped from a hydrocele, measured 52 oz.; the largest quantity on record was that removed from Gibbon, the historian, whose hydrocele when tapped by Mr. Cline, yielded six quarts!

*Signs*.—Serous fluid accumulating in the tunica vaginalis is attended with a swelling on the affected side of the scrotum, which presents certain distinctive characters. This swelling is at first soft and fluctuating under compression with the fingers, but it becomes tense and elastic as the sac is distended; it is translucent when examined by transmitted light. Increasing in size according to the quantity of fluid secreted, the swelling varies in magnitude from a hen's egg to a small cocoa-nut; occasionally, it attains to a size, which dragging over the penis, buries that organ, and extends downwards to or towards the knees. In point of shape, the swelling is at first oval; enlarging, it becomes pyriform with the large end downwards, thus corresponding to the shape of the distended tunica vaginalis; and there is often a slight transverse constriction about the middle of the tumour, apparently due to the lower border of the cremaster muscle, which thus gives an hour-glass appearance to the hydroceleic swelling. Little or no pain is experienced, only some tenderness in the testicle or epididymis; and a sense of weight or dragging-down as the hydrocele enlarges.

The mode of examining a hydrocele is very simple. Having handled

the swelling to ascertain its fluid character, by fluctuation or elasticity; the translucency may be shown by grasping the posterior part of the tumour, so as to render the integument of the fore-part tense; then placing a lighted candle on the one side of the tumour and looking through it from the opposite side; at the same time screening any direct light from the eye, by resting the hand edge-wise along the front of the scrotum.

*Varieties of Hydrocele* are met with, in consequence of changes in the sac, or the contained fluid. These changes are chiefly found in *old hydrocele*. *Thickening* of the sac often takes place, the tunica vaginalis acquiring the resistance of pasteboard; sometimes it becomes cartilaginous, or even osseous by the formation of bony plates on its interior. A *bilocular* or *multilocular* condition of the sac sometimes occurs; either as a result of pouch-like dilatations, or of inflammatory adhesions of the interior and the formation of septa dividing the sac into two or more compartments. The *serous fluid* is liable to undergo the changes of colour and opacity, already noticed.

Under these circumstances; fluctuation and translucency of the tumour become less and less marked as signs of hydrocele. The test by transmitted light may, however, yet be available when the examination is conducted in a darkened room.

*Hydro-sarcocele* signifies that variety wherein the testicle itself is much enlarged in conjunction with hydrocele.

*Diagnosis.*—Hydrocele is distinguished from *scrotal hernia*; by the translucency of the swelling, when this sign is present; by the tumour terminating abruptly at the external abdominal ring, instead of extending with a thick stalk upwards into the inguinal canal; by the sharp angle formed at the external ring, and hinge-like movement of the tumour, when it is tilted forwards; by the absence of impulse at that point, on coughing; by the lighter weight of hydrocele; and by the history of its development, as to whether the swelling commenced below, in the scrotum and ascended to the groin, or descended into the scrotum. The two conditions,—hernia and hydrocele, are not unfrequently *co-existent*; the hernial sac descending into the scrotum, in front, or behind, the hydrocele, on one side of it, or sometimes into the hydrocele. Out of six cases of the latter relative position, which Dupuytren witnessed; in two only, symptoms of strangulation resulted from constriction of the hernia at the line where it was engaged in the serous pouch of the hydrocele. From *cystic disease of the testicle*, hydrocele may be distinguished by the fluctuation extending all over the swelling, instead of being limited to some part of the tumour. From *hæmatocele*, or a collection of blood in the tunica vaginalis, hydrocele is known by its translucency; when non-transparent, recourse must be had to the aid of puncture by a trocar, as the turning point of diagnosis.

*Double hydrocele*, one on each side of the scrotum, occurs in about an equal number of cases.

*Causes.*—The serous fluid in the tunica vaginalis,—forming hydrocele, is only an excessive quantity of that which naturally moistens the internal surface of the tunic; and its accumulation results from loss of balance between secretion and absorption. This change seems to be dependent on long-continued irritation, and often arises from a blow, or other external violence. One of the largest hydroceles I ever knew, was produced by a blow from a cricket-ball. Inflammation may also be induced in like manner; giving rise to hydrocele, and an effusion of lymph mixed with

the serous fluid. Hydrocele occurs most frequently about middle life, and in persons of a weakly constitution, or an enfeebled state of health.

*Treatment.*—Arrest of the secretion and resorption, of the serous fluid, cannot be induced by any known medicinal treatment, topical or constitutional. In this respect, hydrocele resembles similar effusions in hydrocephalus, hydrothorax, hydrops articuli, &c.

The treatment adopted may be *Palliative*, by tapping; or *Curative*, by tapping, and the injection of some stimulating fluid to induce inflammation or inflammatory adhesion; or, as a last resource, by the introduction of a seton for the same purpose.

*Palliative Treatment.*—Tapping a hydrocele is performed by means of a fine trocar and canula, in the following manner. The Surgeon having ascertained the position of the testis, usually at the lower and back part of the scrotum, he grasps the posterior part of the tumour so as to make tense the skin in front; then, selecting a spot about the middle of the projecting surface, and in an interspace between the veins; he thrusts a fine trocar and canula in a perpendicular direction backwards into the hydrocele, taking care not to push the instrument so far back as to wound the testicle, when the hydrocele-sac yields suddenly before the point of the trocar. (Fig. 465.) The object of thus avoiding the veins and of directly transfixing the skin and sac of the hydrocele, is to prevent any effusion of blood into the intervening cellular tissue (Fig. 466), which might lead to sloughing; while the testicle is avoided by observing the precautions in handling the tumour and as to the limited depth of the instrument. On withdrawing the trocar, the fluid is drawn off through the canula, which is then itself withdrawn, and the puncture-spot covered if necessary with a small piece of plaster.

FIG. 465.

The relief afforded by this procedure is, usually, only temporary; the fluid is almost certain to re-accumulate in the course of a few months. Tapping may then be repeated, and on several subsequent occasions, whenever requisite to relieve the weight and inconvenience of the hydrocele. In healthy subjects and small hydroceles, palliative treatment, by a single or repeated tapping, sometimes proves a radical cure.

*Curative treatment.*—This may be effected by means of a stimulating injection, or by the introduction of a seton.

*Injection.*—Tapping having been performed as already described, some stimulating fluid is injected through the canula by means of a small glass syringe. Various fluids have been used; port-wine, spirits of wine, sulphate of zinc in the proportion of a drachm to the pint of water; but the most effectual kind of injection is tincture of iodine, to the amount of two or three drachms. The injection may be allowed to remain in the

sac; or allowed to escape, after the lapse of a short period varying from a few minutes to half an hour, according to the practice of some Surgeons.

Two practical points should be observed in using the injection; firstly, that the slit in the canula be completely within the tunica vaginalis, before throwing in the fluid (Fig. 466); secondly, while withdrawing the

FIG. 466.

canula, the sac should be nipped against it between the finger and thumb. Both these precautions are with the view of preventing any escape of the injection into the cellular tissue between the skin and sac; an accident which would probably be followed by diffuse inflammation and sloughing.

*After-treatment* is simple. The patient should rest for a few days. In the course of twenty-four hours, inflammatory effusion will have taken place into the sac, and the swelling may be reproduced to nearly its original size, looking almost as if the hydrocele had not been tapped. This is a good sign, announcing the probability of a radical cure ensuing. The degree of pain produced is no criterion of the curative efficacy of injection. At the time of operation, sudden and severe pain may occur immediately the stimulating fluid touches the tunica vaginalis, and becomes excruciating; yet

without much if any inflammation being excited. Conversely, there may be little pain and much inflammation. According to the degree of inflammatory swelling induced, it will be necessary to regulate the process; by handling the scrotum on the affected side to promote effusion, or by cold lotions to moderate it.

The cure of hydrocele seems to be effected in two ways; either in consequence of adhesive inflammation, whereby the cavity of the tunica vaginalis is obliterated more or less completely; or, by the mere passing of inflammation upon this membrane, whereby its secretory power is so modified as to restore the balance between absorption and secretion of the serous fluid which naturally lubricates the surface of the tunic. Failures occur; either by an absence of inflammation; or by an excess, with undue effusion or deficient absorption of the superfluous effusion, the tunica vaginalis remaining distended with fluid. Suppuration very rarely supervenes; Sir B. Brodie witnessed it in three cases, and Mr. Curling has seen one such case. Occasionally, the hydrocele has returned, and then gradually disappeared. But generally the cure by injection is permanent, entitling it to be designated the *radical* cure of hydrocele; although sometimes the fluid has returned after a lapse of years.

The *results* of iodine injection have been very satisfactory, both as regards its safety, and success in the cure of hydrocele. It excites inflammation of a moderate and uniform degree, rarely very severe, yet generally sufficient for the purpose. The proportion of failures have been variously estimated; in India, where iodine injection was originally introduced by Sir R. Martin, the failures scarcely amount to 1 per cent.; in France, Velpeau calculates them at 3 per cent. In this country, it has also proved very successful.

*Seton*.—The cure by the passage of a seton should be reserved ex-

clusively for the few cases wherein injection has failed. After tapping the hydrocele, a long needle armed with a seton of silk, is passed up the canula and drawn through the upper part of the scrotum; then the canula is removed, the needle cut off, and the thread knotted loosely. This is allowed to remain until sufficient inflammatory effusion has been induced; usually in a period varying from twenty-four to thirty hours, but occasionally extending to ten or twelve days. Little inflammation may have ensued, yet a radical cure may result. I have never had occasion to employ this method.

The radical cure—whether by injection or seton—should be practised only under certain circumstances, with regard to the size of the hydrocele and the patient's state of health or age. These precautions are necessary in relation to the safety and efficiency of the radical cure.

*Large* hydroceles, one, for example, containing a quart of fluid, should not be injected; the consequent inflammation of so large a sac, might prove overwhelming and terminate fatally. Such a hydrocele may be tapped; and in a short time, emptied again when the sac has undergone contraction; then this smaller sized sac can be safely and effectually injected. An enfeebled state of health, or persons advanced in life, should not be subjected to the risk incurred by injection. Tapping may be resorted to as occasion requires.

*Congenital* Hydrocele presents a few points of importance with regard to its diagnosis and treatment.

The vaginal process of peritoneum remaining open, as a tubular prolongation communicating with the general peritoneal cavity; this condition of the hydroceleic sac gives rise to certain characters, which distinguish it from ordinary hydrocele, and from scrotal hernia. The serous fluid accumulated in the sac can be returned by pressure, into the abdomen, especially in the recumbent position; and the sac gradually refills again when the pressure is removed from the external abdominal ring, and the patient stands up. In both these respects, congenital hydrocele essentially differs from common hydrocele. But it resembles hernia. This may, however, be distinguished by its opacity; and in the non-congenital form of hernia, by the more perceptible presence of the testicle at the lower part of the scrotum.

*Treatment.*—*Repressive* measures, by cold lotions and mild aperients, may sometimes cause the swelling to subside. When repression fails; the hydrocele should be emptied of its contents into the abdomen, by gently compressing the scrotum on the affected side, and a truss applied to the external ring, as for inguinal hernia. The process of peritoneum may now undergo contraction and become obliterated; thus reducing the sac to that of a common hydrocele. Then, in this state; *tapping*, or with *injection* as the radical cure, may be practised.

*Encysted Hydrocele.*—This form of hydrocele consists in the production of a cyst or cysts, containing a thin watery fluid; and projecting from some part of the testis or epididymis. It differs from common hydrocele in its relation to the testicle; being situated above, or below, or to one side, of this organ, instead of enveloping it. Sometimes, however, the cyst projects into the sac of the tunica vaginalis, distending it as if the fluid were contained in its cavity.

The *signs* of encysted hydrocele are, as in ordinary hydrocele, a swelling, fluctuating and transparent; but having the above-mentioned different relations to the testis; and as the cyst increases, the testicle is

borne upon its wall, thus further altering the relative position of the organ. The fluid contained in the cyst is of a thin watery character, instead of being a yellow serous fluid; and it is remarkable for abounding in spermatozoa—a peculiarity discovered by Liston. In both these particulars, the fluid of encysted hydrocele differs also from that of ordinary hydrocele. When this cyst projects into the tunica vaginalis, simulating common hydrocele, the only possible distinction may be, the nature of the encysted fluid as shown by puncturing with a trocar.

*Treatment* is precisely the same as that already described. The radical cure, by iodine injection, is not so uniformly successful as in ordinary hydrocele; but, if it fail, incision of the cyst has been recommended, in order that it may granulate from the bottom and thus become obliterated. Encysted hydrocele may sometimes be left alone; the cyst attaining to a certain size, and then remaining stationary for years.

*Hydrocele of the Spermatic Cord.*—This form of hydrocele is characterized by the presence of a cyst, containing serous fluid; and situated in some part of the spermatic cord. It may be near the testicle, or within the inguinal canal and near the internal abdominal ring; or at any intermediate point. But the cyst is always distinct from the testicle or the tunica vaginalis.

The *signs* are those of a round or oval tumour, rarely attaining to a larger size than a hen's egg; elastic, and translucent when it can be examined by transmitted light. It is moveable, unaffected by compression, and receives no impulse on coughing; unless situated in the inguinal canal, when—owing to its mobility up and down the canal, according to the recumbent or standing position of the patient—the apparent diminution under compression and some impulse on coughing, will render the diagnosis from inguinal hernia most difficult.

The formation of any such cyst in the spermatic cord seems to be generally due to an unobliterated portion of the vaginal sheath of peritoneum which accompanies the cord; and which, at that part, becomes distended by an accumulation of fluid in it. Sometimes, the cyst arises as a distinct cystic-formation, connected with the cord. Hydrocele of the cord occurs most frequently in children or young boys; although it may be met with at all ages.

*Treatment* should be conducted on the same principles as for other hydroceles, by tapping and stimulating injection, or the introduction of a seton; or by an incision to induce granulation from the bottom of the cyst.

*Diffused hydrocele of the Cord*, has been described by Pott and Scarpa; and, as a variety of hydrocele, has found its way into Surgical works. If it ever occurs, it is probably, simply an œdema of the cord, and not any kind of cyst-formation.

*Treatment* would have to be conducted on ordinary principles; counter-irritation by blistering, or incision of any localized swelling to discharge the fluid and provoke consolidation.

**HÆMATOCELE.**—By hæmatocele is meant an effusion of blood into the *tunica vaginalis*; or in a cyst connected with the testicle or cord—*encysted hæmatocele*.

The enclosed blood varies in quantity and condition. In the latter respect, the blood may be a sanguineo-serous fluid, or pure blood. It may be clotted, mingled with fluid, or become uniformly coagulated and laminated in layers, as in an aneurismal sac. Or, the coagula have undergone various states of decolorization and disintegration. The containing

tunic or cyst, usually becomes thickened, perhaps to a considerable extent, amounting even to an inch in thickness, and involving the surrounding cellular texture; as the result of inflammation induced by the presence of effused blood. In hæmatocele of the tunica vaginalis, this thickening involves also the tunica albuginea, but not the substance of the testicle, which remains healthy; although atrophied from constant pressure by the distended sac, or by the contraction of its own thickened tunic. Lymph is sometimes effused, as a product of inflammation, on the inner surface of the tunica vaginalis, there being mingled with the blood.

The *cause* of Hæmatocele is *traumatic*; a blow, or squeeze of the testicle; a strain, as affecting the cord; or other mode of violence. In hæmatocele of the tunica vaginalis; the source of the blood is some ruptured vein in the tunic, or a small rent in this membrane, or it may be a wound of a vessel in tapping hydrocele. *Spontaneous* hæmatocele is also said to occur, apparently from rupture of an enlarged spermatic vein.

In hæmatocele of the cord, rupture of an enlarged spermatic vein is the source of effusion.

*Hæmatocele of the Tunica Vaginalis.*—An effusion of blood into the tunica vaginalis may occur as an original affection, or supervene upon hydrocele.

*Signs.*—In both cases, a swelling is presented, which slowly and gradually increases in size, until it attains to that of a duck's egg or a cocoa-nut, or even to that of a melon. The swelling is more or less fluctuating, and opaque. Sometimes, ecchymosis of the scrotum is produced, whereby the tumour has a characteristic dark-coloured or black appearance; which, however, gradually disappears.

*Diagnosis.*—When the hæmatocele is a primary affection, its sudden appearance is distinctive; especially when the swelling is known to have immediately followed a blow, and is not the product of inflammation. When a hydrocele suddenly enlarges and loses its transparency, an effusion of blood has probably taken place. Ecchymosis of the scrotum, in either case, will confirm the diagnosis. *Chronic* hæmatocele, and without any ecchymosis, may be mistaken for other tumours in the scrotum. The diagnosis must then be determined by the distinctness of fluctuation, the rate of increase of the swelling, and its cause. *Cancer* of the testicle may be mistaken for hæmatocele; in numerous instances, malignant testis has been opened for hæmatocele; and the more serious error has been committed, of removing an hæmatocele for malignant disease. The most constant distinction is the steadily increasing growth of cancer, whereas hæmatocele sometimes ceases to enlarge or even diminishes in size. Puncture of the tumour should always be resorted to as the turning point of diagnosis, before proceeding to remove the testicle.

*Treatment.*—In *recent* hæmatocele, and where the blood yet remains fluid, absorption may, perhaps, be induced; by rest, cold lotions or leeches, according to the inflammatory state of this affection. Even when hæmatocele supervenes on hydrocele; this treatment has proved effectual, without any operative interference.

In more *advanced* and chronic hæmatocele, the state of the blood, as being fluid or solidified, will mainly determine the requisite operative procedure. *Fluid* blood can be evacuated by tapping; and with iodine injection, a radical cure may be effected, as in hydrocele. The admixture of a proportion of blood with serous fluid, will probably not frustrate this method of cure. In hæmatocele, as in hydrocele, the variable position

of the testicle should be remembered in puncturing the tunica vaginalis. Commonly, situated at the back of the sac; the testis was found in front, and was wounded, in two cases recorded by Mr. Curling. *Solidified*, or firmly coagulated blood, cannot be evacuated by puncture; it will then become necessary to make a free incision so as to lay the tunica vaginalis entirely open, to turn out the clots, and wash it out thoroughly by syringing. Otherwise, any remnant blood undergoing decomposition in the sac, sloughing and systemic infection are liable to ensue. Profuse hæmorrhage has, however, been known to follow free incision; a source of danger which cannot be avoided.

When the hæmatocele has attained a very large size, and the tunica vaginalis has become much thickened; castration, in order to remove the entire mass with the testicle, may be the safest procedure. This will be especially advisable in elderly persons.

*Encysted Hæmatocele of the Testis, or of the Cord.*—Cysts, containing blood, are occasionally met with; both in connexion with the testis, and the spermatic cord.

In connexion with the *Testis*, it may be difficult, or impossible, to distinguish encysted hæmatocele from ordinary hæmatocele of the tunica vaginalis. Hæmatocele of the *Cord*, arising from a strain or other violent exertion, presents a cystic swelling in some portion of the spermatic cord; but it is always distinct from the testicle or the tunica vaginalis. Commencing usually within the inguinal canal; the tumour has a round or oblong shape, and increasing in size, it extends downwards through the external ring into the scrotum, where it may attain an enormous size. In one remarkable case, related by Bowman, the tumour, after existing for ten years, had reached down to the patella, and was so heavy as to require both hands and a considerable effort to raise it from its bed. The swelling is semi-elastic, but opaque, when of sufficient size to be examined by transmitted light. As in hydrocele of the cord, hæmatocele of the cord is moveable, unaffected by compression, and receives no impulse on coughing. These characters distinguish it from hernia, unless when situated within the inguinal canal, where the diagnosis is often most difficult.

*Treatment.*—In the *recent* condition of Encysted Hæmatocele,—the blood remaining as yet fluid; remedial measures may be directed to promote absorption, by rest and evaporating lotions. An incision, in this state of the hæmatocele might lead to fearful hæmorrhage from the ruptured vein.

In an *advanced* condition, the mode of treatment must vary according to the fluid or solidified state of the blood. Tapping, or coupled with iodine-injection, will now become appropriate; or an incision, to turn out the coagula, in order that the cyst may granulate and heal from the bottom.

*VARICOCELE.*—An enlarged and varicose condition of the spermatic veins, known as Varicocele, is attended with certain marked characters.

*Signs.*—A swelling, of an ovoid or pyramidal shape with its base downwards, forms between the testicle and external abdominal ring; usually on the left side of the scrotum. This swelling feels knobbed and convoluted; slipping about between the fingers as if it were a *bundle of worms*. It is inelastic and compressible, but the swelling gives a slight impulse on coughing, and it slowly diminishes in the recumbent posture, reappearing in the erect position and increasing after long standing even although moderate pressure be maintained on the external ring. The

enlarged veins may often be seen through the thin scrotal skin. There is little or no pain, but a sense of tension and weight, which is at once relieved when the patient lies down. Sometimes, the swelling becomes temporarily painful. The testicle undergoes a certain amount of atrophy, and when much reduced in size, it may be almost concealed beneath a large varicocele. Double varicocele sometimes occurs, but that on the left side is even then the most developed.

The *diagnosis* of varicocele from scrotal hernia may be readily determined by the peculiar feel of the swelling; although both the tumours have some resemblance, in being affected by coughing and by posture. From hydrocele of the tunica vaginalis, or of the cord, varicocele differs in virtue of all these characters; and as regards the former hydroceleic affection, varicocele has the additional distinction that it does not extend down to the testicle so as to envelope this organ.

The *causes* of varicocele are both predisposing, and exciting. *Predisposition* consists in the anatomical constitution of the spermatic veins;—their size and tortuosity near the testicle, their numerous anastomoses and long efferent trunks, favouring the accumulation of blood, and the loose cellular texture of the scrotum affording little support; while the veins are frequently subjected to pressure by the action of the abdominal muscles. The specially predisposing circumstances usually assigned for the far more common occurrence of varicocele on the left side, are; the slightly lower position of the left testicle, the angle of junction of the left spermatic vein with the renal, and its relation to the sigmoid flexure of the colon as a source of compression. In respect to age, varicocele commences usually at about eighteen or twenty; and in about one male adult in ten. The *exciting* cause may be any exertion which tells upon the spermatic veins; as straining at stool, long walking exercise, standing, or riding. Any such exertion, having induced varicocele, will also aggravate it from time to time.

*Treatment.*—The necessity for any interference with varicocele should be determined by various circumstances; an increasing size of the swelling, the inconvenience or pain occasioned by it; the tendency to atrophy of the testis, and sometimes to spermatorrhœa; with the mental depression induced by this state or resulting from prolonged anxiety respecting the supposed loss of generative power. These circumstances will also indicate the propriety of palliative measures, or of having recourse to the radical cure by obliterating the affected veins.

*Palliative* treatment consists; in wearing a scrotal suspensory bandage or an elastic bag, to support and slightly compress the enlarged veins; or a well-adjusted truss with the pad upon the external ring, to prevent any sudden reflux of blood into the veins during exertion. The latter appliance has proved an effectual cure in some instances, which Mr. Curling mentions, after the truss had been worn some months; and in which the testicle, partially atrophied before the treatment began, regained its natural size. Certain means have also been tried in accordance with the principle of scrotal support, by lessening the *size* of the bag. This has been done by drawing a portion of the scrotum through a soft metallic ring covered with wash-leather, or a vulcanized india-rubber ring; a method of treatment originally suggested by Mr. Wormald. Or, a portion of the scrotum has been excised, with the same object in view; but, this plan is too uncertain as to its efficacy to justify its severity, as a palliative measure.

During any occasional period of pain, or tenderness in the affected

veins; the recumbent posture and rest, a cold evaporating lotion and saline aperients, will give relief.

*Curative treatment.*—Obliteration of the enlarged and varicose veins has been attempted by various operative procedures: by compression with forceps fixed on the scrotum; compression by hare-lip pins and twisted suture; subcutaneous compression between a pin and wire rolled round it; subcutaneous ligature; subcutaneous incision; and by ligature and incision combined.

The methods most frequently practised are; subcutaneous ligature, as proposed by Ricord; and subcutaneous ligature at two points, with intermediate subcutaneous division, as proposed by Mr. H. Lee.

Ricord's *subcutaneous ligature* is thus described by Mr. Curling:—The vas deferens being separated from the mass of veins, and the latter being pinched up with a fold of the scrotum, a needle set in a handle with an eye near the point, armed with a double-looped thread, is to be passed beneath them. When the needle has traversed from one side to the other, the loop is to be drawn out, the needle retracted, and the veins let go, the skin alone being now held up. A second needle, similarly armed, is then to be passed through, over the veins, entering at the same aperture by which the first needle was thrust out, and emerging at the same aperture by which it entered. The second loop is next to be drawn out, and the needle withdrawn. The bundle of veins is thus included between two threads, one passing over and the other beneath it. The ends of the thread on each side are then to be passed into the loop of the other, and by drawing these ends in opposite directions, the veins are tied beneath the skin. The vessels become divided, and the ligatures separate from the tenth to the twentieth day.

A *simple* mode of subcutaneous ligature is that performed by Mr. Erichsen. Having separated the vas deferens from the veins, a small incision is made, about half an inch long, in the front and back of the scrotum; then a needle armed with silver-wire is passed between the vas

and the veins, so as to be brought out behind, and the needle returned in front of the veins; thus these vessels are included in a loop of wire, without implicating the scrotum. The loop is then tightly twisted, whereby the enclosed veins are constricted. By repeated tightenings, the wire gradually effects a passage by ulceration through the veins, which are obliterated by the same process.

*Compression by two Pins, and intermediate subcutaneous division of the Veins.*

—This mode of obliterating the spermatic veins, is the same as that for varicose veins in the leg. The operation is performed in precisely the same way (Fig. 467); care being taken to exclude the vas deferens, which is easily recognised by its round, firm whipcord character.

These operative procedures have been variable in their results. Great relief or a cure has been effected in several instances; and I have been accustomed to practise the last-named operation with a fair proportion of success. On the other hand, no good has been produced, the operation

FIG. 467.

proving abortive; or only a temporary cure has resulted, the varicocele returning at no distant period. Diffuse inflammation and sloughing of the scrotum, or phlebitis and death, have been known to occur. Atrophy of the testis may be mentioned as an occasional result; but this will probably be avoided by not cutting off the supply of blood entirely, in any procedure for obliterating the enlarged veins. The whole of the veins should not be included in the ligature, or subjected to compression and division; and the spermatic artery should be excluded, a precaution easily observed by keeping free of the vas deferens, near which the artery lies.

**INFLAMMATION OF THE TESTICLE.**—This subject comprises *Orchitis*, when the testicle itself is the seat of inflammation; and *Epididymitis*, when the epididymis is primarily affected. *Chronic* Enlargement of the testis or of the epididymis, resulting from special causes of inflammation, may be Syphilitic or Scrofulous. These affections will be afterwards considered.

**ORCHITIS and EPIDIDYMITIS.**—Inflammation of the Testis occurs less frequently than that of the Epididymis. But either part being primarily affected, the other becomes involved; and thus Orchitis and Epididymitis are usually found associated.

*Symptoms.*—Swelling arises, which has the characteristic shape of the part wherein the inflammation is seated; whether the testis, presenting an ovoid swelling; or the epididymis, when its inferior globus presents a nodular enlargement, or the whole of the epididymis, in the form of an elongated mass at the back of the organ, can be readily distinguished. As the swelling rapidly increases, it soon becomes tense and hard, especially in the testis, owing to the resistance of its more unyielding tunic; and it attains to a considerable size, that of an orange or even a small cocoa-nut. Effusion often takes place into the cavity of the tunica vaginalis, as well as into the substance of the gland, of the epididymis, or of both these structures; and thus the swelling may be exaggerated beyond what really pertains to the testicle. Pain accompanies the swelling, and it increases in severity proportionately to the tension of the part; with a sense of dragging weight, or a dull, heavy aching, and sickening pain, extending up the cord into the groin, iliac region and loins. The scrotum becomes tender, distended and reddened, exhibiting also a congested state of the serotal veins; as the integument and sub-cellular texture participate in the inflammation. Sharp inflammatory fever attends the development of the disease; and there is usually considerable nausea or even vomiting and constipation, simulating strangulated hernia.

*Causes.*—Various *injuries* of the testicle and sources of *urethral irritation*, may give rise to orchitis or epididymitis; and certain constitutional diseases have a predisposing influence, or may directly induce these inflammatory affections. Thus, exciting causes comprise; a blow, squeeze, or wound, of the organ; urethral irritation, especially near the orifices of the seminal ducts; as by gonorrhœal or other inflammation of the urethra, stricture, or the introduction of instruments, the impaction in, or the passage through, the urethra, of a calculus; injury to the vas deferens in lithotomy or in puncture of the bladder per rectum. The various sources of irritation in the urethra, or occasions of injury to the seminal ducts, more commonly give rise to epididymitis than to orchitis; although the testis often becomes secondarily inflamed.

The causative *operation* of urethral irritation in exciting inflammation of the epididymis, is doubtful. It does not arise from gonorrhœa until

the urethral inflammation is subsiding, and when perhaps discharge alone remains. Some slight external cause of irritation, such as active walking exercise, riding on horseback, or the friction of tight trousers, may then produce epididymitis. Sudden suppression of the urethral discharge seems to give rise to this inflammation, by *metastasis*; or the discharge continuing, it would appear that the morbid action extends along the *vas deferens* from the urethra to the testicle. But of this mode of causation, there is no sufficient evidence. The inflammation can only be designated *sympathetic*.

Of *constitutional* causes; mumps more frequently affects the testis than the epididymis, but the inflammation may commence in either part and extend to the other; syphilis, scrofula, gout and rheumatism, especially gonorrhœal rheumatism, may also severally predispose to, or induce, inflammation either of the testis, or of the epididymis. Excepting however, syphilis, which chiefly affects the testis; the scrofulous, gouty and rheumatic diatheses, generally induce epididymitis, the testis becoming secondarily affected.

*Terminations*.—Acute inflammation of the testicle or of the epididymis, usually subsides by *resolution*, in a period varying from a week to a fortnight or longer. As the disease declines, the distinctive characters presented by the enlargement of the two constituents of the organ, again become apparent. The testis first resumes its natural size and shape; the epididymis often continuing enlarged, irregular, and hardened, for a considerable period. Ultimately, when the structural condition of the organ is restored, its functional power remains unimpaired. *Atrophy* is sometimes the result of inflammation; exceptional cases of this kind, in consequence of mumps, have been seen by Dr. Hamilton, M. Rilliet, and Professor Humphry. *Suppuration* rarely occurs, though I have seen it in one case.

*Treatment*.—In the *acute* stage.—Local blood-letting is a most effectual means of subduing the inflammation, whether as orchitis or epididymitis. Blood may be abstracted by the application of leeches to the scrotum, or by puncturing the congested scrotal veins. The latter method is preferable, as leech-bites are apt to become centres of inflammation. Puncturing is most conveniently commenced at the lower part of the scrotum, so that the blood trickling from the veins first opened, shall not obscure the vessels above. Warm fomentations should then be applied, whereby double the quantity of blood may be drawn off than would otherwise be abstracted. Six or eight ounces of blood having been taken in this way, rest in the recumbent position with the scrotum well supported by a pillow or handkerchief, will complete the local treatment in the acute stage of inflammation. It has been proposed to puncture the *tunica albuginea* at different points, in order to reduce the tension resulting from this fibrous tunic; and I have heard that great relief and even a cure, has been thus speedily obtained, in several instances. I have had no experience of this resource; but it would seem to be at least unnecessary, seeing that the inflammation is amenable to ordinary antiphlogistic measures. *Constitutional* treatment consists, in the administration of antimonial saline aperients, combined with hyoscyamus or other sedatives. When, indeed, the inflammation follows gonorrhœa; hyoscyamus in full doses with camphor mixture, will, I have found, often prove sufficient to subdue the pain and swelling; unaided by any other medicinal agents. This method of treatment, was I believe, originally proposed by Mr. Gay.

Pressure, as by means of strapping the testicle, has been highly recommended in the acute stage, by Fricke of Hamburg; but at this period, it generally increases the inflammation, or at least intolerably aggravates the pain.

*Chronic enlargement*, resulting from acute inflammation, is best reduced by strapping. Simple adhesive plaster may be used; or the em-plastrum ammoniaci cum hydrargyro and soap-plaster, as affording both pressure and a stimulant application.

*Strapping* a testicle is a simple proceeding, but requires to be done so as to give uniform support. Several strips of plaster must be provided, each about an inch broad, and of sufficient length to embrace the enlarged testicle, vertically and horizontally. The scrotum having been shaved, it should be drawn well upwards on the side of the enlargement. Then, a long strip of plaster is passed from under the scrotum above the enlarged testicle, and brought round the corresponding side of the scrotum, so as to isolate the testis from the opposite side. Strips are then passed in succession, longitudinally and horizontally, each strip overlapping the next, and drawn moderately tight; thus uniformly enveloping and moderately compressing the whole organ. Care should be observed not to strangle the scrotum above, as sloughing has been known to ensue.

*Chronic Enlargement of the Testicle, or Sarcocoele.*—This condition of the Testicle may be the result of *simple* inflammation, having a traumatic origin; or it may be a manifestation of certain *constitutional* diseases,—Syphilis or Scrofula. Thence, three varieties of Sarcocoele may be recognised, in regard to their *origin*. But the attempt to carry their distinction further has failed to establish any *essential* points of pathological difference;—in respect to the structural condition of the chronic enlargement, its signs or external characters with regard to diagnosis, and its terminations. The peculiar treatment requisite will of course depend upon the origin or cause of the Sarcocoele.

These remarks apply more especially to Syphilitic and Scrofulous Sarcocoele. In considering the general pathology of the Constitutional Diseases, of which these two varieties of Sarcocoele are, occasionally, local manifestations; their structural conditions, signs, and terminations, were sufficiently described. It remains only to consider the treatment of these conditions of the testicle, with a recapitulation of their pathology.

*Syphilitic Sarcocoele.*—In this variety of chronic enlargement of the testicle, the gland itself is chiefly affected, and less frequently the epididymis. It consists of a fibrinous deposit, in the form of nodules, situated in the *interstitial connective tissue* of the glandular structure, in the septa, mediastinum, and tunica albuginea; and sometimes extending into the connective tissue of the epididymis. Thence, the organ becomes considerably enlarged, to the size of a turkey's egg, or perhaps of a cocoa-nut; it has an ovoid shape, is heavy, hard, and *nodulated*. But, when the deposit is principally central, the organ may be smooth externally. An effusion of fluid sometimes takes place into the tunica vaginalis, constituting hydro-sarcocoele; a condition which masks the enlargement of the testicle, until the fluid is evacuated. There is little or no pain, only the inconvenience of the dragging weight. The diagnosis, however, must be determined by the syphilitic history.

The *consequences* of this enlargement are; atrophy of the glandular structure, owing apparently to contraction of the interstitial fibrinous deposit; as in cirrhosis of the liver. Nevertheless, the tubuli seminiferi

sometimes become involved; their walls being thickened and blended with the intervening tissue, according to Virchow, while the epithelium lining them undergoes pigmental and fatty degeneration. The function of the organ will be proportionately and permanently impaired or destroyed. This tendency is particularly noticed by Vidal (de Cassis), who, however, gives instances of recovery of function in testicles which had been severely invaded by syphilitic orchitis. Suppuration may ensue, as a consequence of the chronic enlargement; forming an abscess in the substance of the testicle. The pus may degenerate into a caseous, calcareous or earthy mass; but usually, the abscess increasing, at length contracts adhesion with the tunica vaginalis and scrotal integument, and then bursts through the tunica albuginea, and discharges externally. The aperture having continued for a time, closes permanently; or a succession of abscesses, form, burst, and heal. Any such abscess of the testicle having burst, is not unfrequently followed by ulcerative enlargement of the aperture, and protrusion of a portion or whole of the organ,—forming hernia testis. The integument thickened and indurated, constricts the protruded portion; and granulations springing up, give an expanded appearance to the protrusion, beyond what is really testicular.

*Treatment.*—When syphilitic sarcocele has not been long established, the deposit may be influenced somewhat to undergo absorption, by means of medicinal agents; without injuriously affecting the general health, or damaging the remaining tissue of the organ. A mercurial course, combined with tonics, often proves beneficial; the bichloride of mercury, in doses of the twelfth or eighth of a grain, with quinine, three times a day, and continued for six or eight weeks. Iodide of potassium may then be advantageously substituted, until the hardness and swelling disappear. *Strapping* the testicle, as already explained, with adhesive or mercurial plaster, is less effectual in promoting absorption; and occasionally it seems to arouse the inert deposit to suppuration.

*Scrofulous Sarcocele*—This variety of chronic enlargement of the testicle differs only from that of syphilitic origin, in two particulars; generally, the epididymis, and even the vas deferens, is primarily the seat of scrofulous deposit; and this is at first contained *within* the tubules. The *nodular* form of enlargement is usually presented; and as the testicle itself soon becomes implicated, the whole organ is enlarged and irregular, at an early period of the disease. Tubercular deposit, in the form of gray, semi-transparent, granular tubercles—as found in the lungs—represents the kind of deposit in the enlarged testicle; thence named *tuberculous* sarcocele. Hydrocele sometimes ensues, disguising the testicular enlargement, until the fluid is evacuated.

The almost painless character of the disease, as in syphilitic sarcocele, reduces the diagnosis of these two varieties of sarcocele to the external characters of the enlarged testis; and as these are not positively distinctive, the nature of the disease can only be determined by the co-existence of other Scrofulous affections or tendencies. Thus, the condition of the lungs should be examined, and that of the prostate and seminal vesicles; the latter parts being not unfrequently also enlarged by scrofulous deposit.

The *consequences* of scrofulous sarcocele are not peculiar; but the tendency to suppuration and abscess, followed by hernia testis, is even more marked than in syphilitic sarcocele. There is also abscess in the epididymis extending up the vas deferens, and converting their hardened enlargement into a fluctuating bag of pus.

*Treatment.*—Constitutional and hygienic measures are more likely to prove beneficial than any local treatment. Tonics, principally iron or the iodide of iron and quinine, with cod-liver oil, should be taken for a considerable period; the diet must be well regulated, and other means adopted for the improvement of the general health. At the same time, the iodide of lead ointment, and strapping the testicle, may have some locally curative influence of subordinate importance.

*Abscess* in the Testicle, as the result of inflammation of this organ, occurs sometimes from syphilitic orchitis, but more commonly from scrofulous orchitis. The *signs* of this condition are in no way peculiar, and the *treatment* must be conducted on ordinary principles.

*Hernia Testis*, or protrusion of the testicle, is apt to follow the bursting of an abscess. The appearances have been already described. It presents, usually, a red, granular, fungous mass; but varying according to the state of inflammation, sloughing, or granulation. The mass becomes expanded over, and is constricted by, the margin of the aperture in the conjoined tunica albuginea, tunica vaginalis, and indurated scrotal integument.

*Treatment.*—According to the *size* of the protrusion, the attempt may be made to repress it, or it will be necessary to remove the mass. When of small size, a cure may often be effected by pressure; some lint or charpie spread with the ointment of red oxide of mercury is laid upon the protrusion, and well strapped down with strips of plaster. Or, the integument may be detached on either side of the protrusion, the edges pared, and brought over it in front, and retained by suture; pressure being thus applied, as suggested by Mr. Syme. Another plan, devised by Dr. Pagan of Glasgow, consists in dissecting down to the tunica albuginea, and then incising the margin of the aperture in that tunic, like the ring in strangulated hernia. After this, the treatment is said to be much more successful.

When either of these plans have failed, or the protrusion is of larger size; it should be removed by shaving it off with a bistoury. During the process of granulation, the tendency to exuberance and reprotrusion should be repressed by dressing with the mercurial ointment, with strapping.

If nearly the whole organ be protruded, or the portion left by excision be found diseased; it will be better to have recourse to castration. The remnant portion of testicle would be of no functional use, and would slough away, prolonging the cure.

**TUMOURS.**—The testicle, like other organs, is liable to be the seat of various morbid growths, forming Tumours; all of which are distinct in their nature from Chronic Enlargement or Sarcocoele, as resulting from any kind of morbid deposit,—Syphilitic, Scrofulous, or Tuberculous.

Tumours of the Testicle, thus pathologically distinguished, may be; Cystic; occasionally, Cartilaginous, and Fibrous; or Cancer,—Encephaloid and Scirrhus. These various testicular Tumours are sometimes described as additional forms of Sarcocoele, a misleading designation respecting their real nature.

**CYSTIC TUMOUR OF THE TESTICLE.**—This form of Tumour, known also as the Hydatid Testis of Sir A. Cooper, may be purely Cystic; or associated with Cartilaginous, or with Cancer Growth.

Cystic Disease consists of an agglomeration of cysts, thin-walled, varying in size from a pin's head to a walnut, and their globular shape modified by mutual pressure. They are *simple* cysts; containing fluid,

thin and colourless, or viscid and blood-tinged or otherwise discoloured; or they become *proliferous*, bearing on their interior fibrous growths, of a pedunculated, and lobulated shape, which occupy and eventually distend the cysts. These intra-cystic growths have been found by Mr. Quekett to possess a cellular structure covered on the surface with cylindrical epithelium, and they may contain small, hard, spherical bodies like pearls, composed of concentric layers of condensed epithelium. Fibrous tissue, in variable quantity, is formed with, and intervenes between, the cysts. When constituting the chief element of the tumour, this has been named *fibro-cystic* tumour. Thus Mr. Paget describes the cystic growth, as essentially a fibrous, or fibrous and cartilaginous, tumour in the testicle, with more or less cyst-formation in its substance.

The growth is not generally diffused throughout the organ; it originates, and remains circumscribed in one part; and as the growth increases, the unaffected portion of the testicle is pressed aside or spread out over the tumour; so that the mass, which is usually spherical, can perhaps be shelled out, leaving a considerable part of the testicle healthy. Occasionally, gland tissue has been found dispersed to a certain amount, through the cystic tumour. The epididymis, at first unaffected, becomes flattened, compressed, and atrophied.

The primary situation, and mode of origin, of the cysts, are doubtful. They appear to originate in the substance of the organ; but whether in the tubular gland tissue, or in the connective tissue, is uncertain. And the mode of cyst origin may perhaps be, a dilatation of the seminal tubules, as Sir A. Cooper originally stated, and Mr. Curling seems to have confirmed; or the cysts may originate as independent formations. Respecting the probability of the former mode of origin, it is a remarkable fact that spermatozoa are never found in the cysts.

*Signs and Diagnosis.*—The testicle enlarges, acquires an oval or nearly spherical form, and slowly attains to a considerable size. Its weight is less than that of any solid tumour, but it is heavier than hydrocele. Elasticity, over a limited area, with less decided fluctuation, and a total absence of transparency; will chiefly distinguish cystic testicle from hydrocele. The painless character of the tumour, and absence of constitutional symptoms, with the slow rate of growth; may determine the diagnosis as with regard to encephaloid cancer of the testicle. But the distinction between cystic-growth and non-transparent hydrocele, hæmatocele, and cancer, cannot sometimes be arrived at with certainty except by the aid of puncture to examine the nature of the fluid yielded, and at several points of the tumour. Cystic-testicle is most frequent between twenty and fifty.

*Treatment.*—Castration is the only cure; and it may be resorted to at an early period, especially when the other testicle is healthy and functionally efficient. As in the case of other double organs, the remaining testicle will probably acquire the power of doing double duty. The disease never returns, a therapeutically important distinction as compared with Cancer.

*Cartilaginous-Growth or Enchondroma*, is often associated with Cystic Tumour. The cartilage usually exists in the form of nodules, which apparently grow from and occupy the interior of the cysts; as a cartilaginous variety of proliferous cysts. These nodules are sometimes strung together into lines; apparently indicating that the cysts had formed by sacculated dilatations of the seminal tubes of the testis or its rete, in accordance with Curling's interpretation of cystic testicle. The cartilaginous structure may undergo calcification or ossification.

This structural admixture of cartilage, or of its transformation, with cysts, modifies the *signs* of cystic tumour of the testicle; by giving hardness and weight to the mass. But any such complication in no way contra-indicates the treatment by castration, nor affects the success of its result.

*Cancer-Growth* is not unfrequently associated with Cystic Tumour; this growth also taking place from the interior of the cysts, as a cancerous variety of proliferous cysts. The kind of cancer is encephaloid, and it forms in some parts of the tumour, leaving the remainder simply cystic; but ultimately perhaps invading the whole mass.

The *signs* of cystic testicle are modified accordingly; and although the treatment must still be castration, yet the result of the operation, as to a return of the disease, will be uncertain.

FIBROUS TUMOUR OF THE TESTICLE, is generally enumerated among the Tumours to which this organ is liable. An apparently well-marked specimen is described by Cruveilhier. Its consistence was very firm, and it creaked under the scalpel; the weight of the tumour was heavy in comparison with its size, which was twice that of the natural size of the testicle. In point of structure, when examined, it was found to consist of contorted and interlaced greyish-white fibres forming lobules, with vessels penetrating their interspaces; thus certainly confirming the nature of this tumour. Sir B. Brodie describes a less well-marked specimen, which he removed by castration. Mr. Paget speaks of a "fibro-cellular tumour," removed in like manner, by Mr. John Lawrence; and which was so succulent, that, in its consistence, it resembled a fatty tumour.

CARTILAGINOUS TUMOUR OF THE TESTICLE is sufficiently noticed in connexion with Cystic Tumour. These two forms of growth are so very frequently associated in the same Tumour, that the pathology and treatment of Enchondroma of the Testicle, as an independent form of Tumour, need not be considered separately.

CANCER OF THE TESTICLE usually occurs in the form of *encephaloid*, or occasionally its melanotic variety; rarely in the form of *scirrhus*.

*Encephaloid* cancer commences most frequently in the glandular portion, as small masses among the tubuli seminiferi; and these increasing, coalesce, to the destruction of the glandular substance. Less frequently, it begins at one point in the centre of the testis, or in the rete; and occasionally in the epididymis. From either of these sources, the growth invades the whole organ, reducing it to a cancerous mass, without any trace of the natural structure.

The encephaloid mass has, as usual in this species of cancer, a soft pulpy consistence, and commonly a more or less uniform white or pinkish-white colour. As the proportion of cancer-cells, or of the containing filamentous areolar stroma, predominates; so is the cancer substance developed, or the mass assumes the characters of a fibrous tumour. Or, the cancer-tumour may be associated with cyst formation, or with cartilaginous structure, in its substance. Thus, then, all the forms of morbid growth to which the testicle is liable, may be associated in one and the same Tumour. Hæmorrhage is apt to occur in the substance of Encephaloid Testicle, from any slight blow or external injury; and the blood may be effused interstitially, or into irregular cavities produced by its pressure. As the cancerous testicle increases, with a tolerably steady, but on the whole, rapid progress, it attains to a large size; the tunica albuginea yielding under pressure to a very great extent without rupture.

At length it bursts, and the mass protrudes as a bleeding fungus through the ulcerated skin. The disease extends along the cord to the abdomen, and the lumbar glands become involved; secondary cancer also being developed in other organs. Death ensues; usually, in about eighteen months or two years.

*Signs.*—Enlargement of the testicle, as a solid heavy tumour, of rapid growth, is the almost infallible indication of Encephaloid cancer. The unbroken tunica albuginea gives a hardness uniformly over the tumour, and a smoothness of surface, which really does not belong to encephaloid cancer; and which ceases subsequently, as the mass softens at parts into an elastic, pulpy, semi-fluctuating tumour, or when the tunic is ruptured and the mass protrudes. There is commonly little tenderness, or pain; or if there be, it is dull, not acute or lancinating. When the cord has become involved, it is enlarged, and feels thickened and full; so that the vas deferens cannot be distinguished. Shooting pains extend along the cord to the groin and loins. As the disease advances, constitutional symptoms are evinced by cachexia, and a breaking down of the general health; the patient having been at an early period of the disease, often in a robust, fleshy, and florid condition of health. The age when cancer of the testicle most commonly occurs, is from twenty to forty; it is rare after sixty, but it may occur at any period of life, from the earliest infancy to old age.

*Diagnosis* from other tumours of the testicle is mainly determined by the solidity and weight of Cancer-Tumour, with its rapid growth; but it must be distinguished from acute orchitis, and from chronic enlargement of the testicle,—syphilitic or scrofulous. The symptoms of inflammation, or the constitutional condition, respectively exclude these *Swellings* of the testicle from the question of diagnosis; and the various forms of Tumour are severally excluded by reference to the above-named characters. Thus, Cancer-Tumour of the testicle differs from *Cystic* Tumour in all these particulars,—its solidity, weight, and rapidity of growth; from *Fibrous* Tumour, if such should occur, it differs in the far greater rapidity of growth; and from *Cartilaginous* Tumour, the difference in this respect is equally significant. As compared with *non-transparent Hydrocele*, and with *Hæmatocele*, respectively; the solidity and weight of Cancer-Tumour are equally distinctive. But often the diagnosis can be accurately determined only by puncture of the Tumour, in order to subject to microscopic examination, the substance or fluid from the mass, in question.

*Scirrhus*-cancer far less frequently affects the testicle; a few examples only of this form of the disease having been recorded.

The *signs*, as distinguished from encephaloid cancer, are; greater solidity, hardness, and weight of the testicle, but the tumour is not disposed to attain so large a size. It is characterized also by slow growth, and the disease occurs at a later period of life.

*Treatment of Cancer of the Testicle.*—Castration is the only cure; provided that the whole of the disease can be thus removed. Consequently, when the disease is entirely local, affecting only the testicle; castration may be performed, and with an equal chance of success, as after similar operations for cancer in other parts. When, however, the spermatic cord is involved, and perhaps also the lumbar glands, presenting a tumour more or less perceptible in the abdomen; castration will be unjustifiable.

The *results* of the operation have been unsatisfactory both in the localized and extended conditions of the disease. Thus, in the latter condition; of 36 cases collected in the Medical Times and Gazette (vol. xix.), 3 died within a week, and cancer was found in the lumbar glands; 2 died within six weeks; and 2 within three months of the operation. In each case, there was disease of the lumbar glands, or lungs, or both. When the disease, being local, has been completely extirpated, the tendency to secondary cancer, particularly in the lungs, is remarkably strong; and life may be prolonged only by a short period. One patient, under Professor Humphry's observation, lived four years, and died, as was believed, of phthisis. But a similar period of existence, in another case, was known to Sir B. Brodie, and the patient then remained well. Mr. Curling also relates four cases in which the patients were well at the respective periods of 10, 4, 9, and 12 years, after the operation. On the other hand, without operation; in 2 of the above-mentioned 36 cases, the disease terminated fatally in a period of four months from the time it was first observed in the testicle; but cases have been recorded in which life continued for 5, and even 15, years!

CASTRATION.—Removal of the testicle is a very simple operation, but certain practical directions of importance should be observed. The pubes having been shaved on the side of operation, the patient should be drawn to the end of the table; so that resting there on his buttocks, the thighs and legs shall hang down, and give fair room for handling the tumour. The surgeon standing in front, between the patient's legs, grasps the tumour posteriorly with his left hand, making the scrotum tense in front. Then, a bistoury is entered opposite the external abdominal ring, in order to reach the cord sufficiently high up that when it comes to be divided, the cut stump, which is apt to retract, shall be freely accessible for ligature of the vessels. On this account, it may sometimes be advantageous to expose and isolate the cord, before removing the testicle from the scrotum. The incision is carried down longitudinally, from the external ring, over the anterior surface of the tumour to the bottom of the scrotum; or if the mass be of very large size, or the skin affected, a double elliptical incision may be made enclosing a portion of the scrotum; it will seldom be requisite to remove any apparent redundancy of healthy integument, as the scrotal skin contracts and shrivels up very considerably after the operation. The tumour is readily turned out of the scrotum by a few touches with the knife, dividing its loose cellular connexions; on the inner side, the knife should be particularly turned outwards, towards the tumour, in order to avoid puncturing the urethra, or opening the tunica vaginalis of the opposite side. Having detached the testicle and isolated the cord, the latter is seized between the thumb and finger by an assistant, or with a vulsellum, and held in position. The cord is then divided by a stroke of the knife below this point, and the testicle completely removed. The spermatic artery, and probably two or three cremasteric branches, will require ligature. This mode of securing the vessels is preferable to tying the whole cord, a practice adopted by some surgeons. But if there be any fear of retraction of the cord through the ring into the inguinal canal, it should be ligatured and retained in position by a strip of plaster over the ends of the thread. Scrotal vessels generally cease to bleed by sponging with cold water. Sutures are not required, the edges of the scrotal integument falling into apposition; and

the wound, being dressed with a strip of wet lint, heals by granulation from the bottom.

In the after-dressing, bagging in the lower part of the scrotum must be prevented. Secondary hæmorrhage may necessitate a reopening of the scrotum, which must then be lightly stuffed with wet lint. Retraction of the cord into the inguinal canal, would render it very difficult to follow up the source of hæmorrhage in that situation; and a serious or even fatal loss of blood might ensue, by its escape into the cellular texture of the groin and pelvis, without much external hæmorrhage.

ATROPHY OF THE TESTICLE may occur as the result of various structural conditions, which have already been described. *Hydrocele* is an occasional cause, by pressure of the fluid in the tunica vaginalis; and sometimes in consequence of the contraction of lymph effused in chronic hydrocele, or more frequently in *Hæmatocele*. *Diseases* of the testicle, also, result in absorption of the glandular substance; somewhat in proportion to the extent and persistence of any morbid deposit, or the formation of new growths, within the testis. Thus, atrophy may ensue from orchitis, acute or chronic; and more especially in the chronic form, with syphilitic intertubular deposit, or with scrofulous intertubular deposit. Obliteration of the *vas deferens* from inflammation, or from pressure by constantly wearing a truss, has been known to induce atrophy of the testis; although the function of the organ may be thereby long suspended or lost without this result. *Varicocele* is an occasional cause, and obliteration of the spermatic veins by *operations* for the cure of this condition. Elephantiasis of the scrotum may be mentioned, as having the same effect. *Functional excitement of the organ*, from excessive venery, or from self-abuse, has an atrophying influence; and *injury* of the back of the head, a similar tendency, apparently by affecting the cerebellum. In *elderly persons*, the testes are rather small and flaccid, but otherwise healthy; and the epididymis is sometimes thickened and indurated, with a similar state of the vasa deferentia, and opaque white spots in their walls.

No particular *Treatment* can be directed for a condition, the causes of which are so diversified and often irremovable.

FUNCTIONAL DISORDERS OF THE TESTICLE, are associated with Functional Disorders of the whole Generative Apparatus, constituting Spermatorrhœa and Impotence.

*Spermatorrhœa*, or Seminal Emissions, easily excited and oft recurring. This disorder may occur; either, as *passive* discharges of seminal fluid, without much, if any, ejaculation or even previous erection, or, as emissions, with *spasmodic* ejaculation and perhaps erection. In the one form of the disorder, seminal discharge takes place before erection; in the other, erection and ejaculation are often simultaneous acts, or erection may subside before ejaculation. In both conditions therefore, connexion is impracticable; and thus there is loss of sexual power, and apparently, at least, of procreative power.

*Passive Spermatorrhœa* denotes an excitability of the testes as secretory organs, whereby an excessive secretion or flux of seminal fluid is easily provoked, usually of a thin spurious character; and accompanied with irritability of the ejaculatory muscles, and of the erector muscles of the penis; while the constitutional condition is one of general debility.

The common *cause* of this state of mixed generative irritability and constitutional debility, is habitual masturbation or self-abuse. This

pernicious habit is acquired often at an early age, before puberty, by evil example or conversation among boys, who are intimately associated in Schools and other Institutions. A practice thus engendered, before moral control has yet been developed, and indulged in ignorance of its sad consequences, may be rectified only perhaps by marriage, or perhaps continued until it has wrecked its victim,—physically, intellectually, and morally. Spermatorrhœa is less frequently the consequence of suppressed sexual desire. It seems also more common in the upper and middle, than in the lower ranks of life, regarded socially; and among the educated and studious, than among those who have early followed some bodily avocation, or have been accustomed to the healthful games and outdoor pastimes of youth.

At first, seminal emissions happen only occasionally; once a fortnight or in a week, and usually in the morning between sleeping and waking, or as nocturnal emissions. After a while they become more frequent, perhaps three or four times a week, and occur during the day; under any slight emotional excitement, a word or even a look; or from some slight irritation, as by the movement of a carriage, or by any straining exertion, especially at stool. Ultimately, the emissions occur every twenty-four hours, and sometimes twice or thrice daily; the semen flowing back into the neck of the bladder, and escaping with each act of micturition or defæcation.

The physical consequences of spermatorrhœa, are evinced by general debility, and disorder of the various functions; indigestion, palpitation of the heart, breathlessness, nervousness, epileptic, and amaurotic symptoms, or even paralysis. The intellectual and moral decay are manifested by a general impairment of mental vigour; especially, inability to fix the attention, and loss of memory; and by loss of moral courage, great depression of spirits and despondency or despair, shyness, reserve, and solitariness. Altogether, the pallid, vacant-looking, dejected, and lonely, victim of spermatorrhœa, in its advanced stage, is a wretched spectacle which can scarcely be mistaken. He is often made worse, and his mental sufferings are aggravated, by reading some of the abominable and lying publications of quacks and extortionists; he is thus also entrapped into their dens, where his worst fears are speedily confirmed by personal influence, and his pecuniary resources drained to the last shilling, or incredible sums abstracted for promised cure. In one such case of imposition, a gentleman came to me for relief, whose penis was strangulated at the root by means of a broad metallic ring, furnished with a screw which tightly compressed a plate of metal on the urethra; the whole contrivance forming a vice in which his penis had been placed by one of the daily-advertising impostors, and which he had been ordered to wear for the ostensible purpose of stopping seminal emissions. Of course, the pain of approaching strangulation daily increasing, daily compelled the patient to visit his merciless torturer; and when the poor victim came to me, his penis had become swollen to the size of a Saveloy-sausage, burying the vice, and the integument was rapidly passing into gangrene. I removed this instrument of torture, only just in time to save the organ.

*Spasmodic Spermatorrhœa* differs only from the more passive form of seminal emissions; in the increased irritability of the ejaculatory and erector muscles of the penis, and of the prostatic portion of the urethra where the ejaculatory ducts open. It is not unfrequently co-existent with some disease of the generative organs,—stricture, varicocele, or neu-

ralgia of the testicle, which may be the source of local irritation. Residence in a hot climate seems to have some predisposing influence; and the affection occurs usually at a later period of life than passive emissions in men, from the ages of twenty-five to forty.

*Treatment.*—The removal, if possible, of any source of *irritation*, is the primary indication. Thence, the habit of masturbation must be corrected, whenever its practice can be discovered; and the patient should be encouraged to make a confidential acknowledgment respecting a matter of such vital consequence to his health and happiness. The influence of evil example should also be withdrawn, in youth; and the mind of an adult patient may have to be disabused of the groundless apprehensions which have been instilled into it by some rapacious impostor. Any source of local irritation, as a cause of spermatorrhœa, must be removed, when practicable.

*Remedial treatment* comprises both constitutional and local measures. *Constitutional treatment* consists in the administration of tonics to restore a healthy state of both the muscular and nervous systems, and in the use of sedatives to allay irritability. Of tonics, the preparations of iron are most efficacious; and particularly, the sesquichloride of iron, in doses of from 15 to 30 drops in half a wine-glassful of water, thrice daily. Strychnia, in doses of the  $\frac{1}{12}$  of a grain, made into a pill, with or without the sulphate of iron; forms a tonic anti-spasmodic preparation of great value. Sedatives are less beneficial than tonics; yet in spasmodic spermatorrhœa, a night-pill of belladonna, or of hyoscyamus and camphor, may perhaps be advantageously given to subdue the local irritability which favours the seminal emissions. Suppositories of pil. saponis, 10grs., are, according to my experience, preferable as acting topically. The cold hip-bath, or sluicing the perineum with cold water, night and

FIG. 468.

morning, is a most serviceable local tonic. *Hygienic measures* must also be carefully attended to, as a part of the constitutional treatment. A plain, unstimulating, nutritious diet, is essentially requisite; rigorously excluding peppers and other condiments, which are apt to irritate the rectum and provoke seminal emissions during defæcation. The stomach should never be overloaded by a heavy meal; and a daily action of the bowels should be secured by gentle aperients, when necessary. A dinner-pill, consisting of the compound rhubarb-pill with hyoscyamus, will answer this purpose far better than colocynth or any other irritant purgative. The invigorating influence of daily exercise in the open air, and of out-door amusements, with perhaps recourse to a bracing climate, can scarcely be overlooked; but relaxation from study or the excitement of business, and freedom if possible from the pressure of anxiety, are no less restorative; while every encouragement must be given to cheerfulness and hope.

All this constitutional treatment not unfrequently fails to cure the spermatorrhœa; the local irritability of the prostatic urethra still remaining. Recourse must be had to the application of nitrate of silver along the under surface of this portion of the urethra, to the orifices of the ejaculatory ducts.

This method of treatment, first prominently brought into notice by Lallemand, can be effected by means of the *porte-caustique* (Fig. 468), or by a *syringe-catheter*. The former instrument is also a kind of catheter, but which acts by protruding its end, carrying the caustic. This portion, however, is apt to be grasped by spasmodic muscular action, and can then be returned only with difficulty into the shaft; or it may perhaps become fixed in the prostatic urethra, owing to some defect in the instrument, as happened in the person of a gentleman on whom Dr. Humphry was operating. In the syringe-catheter, a piece of sponge charged with a solution of the caustic, is compressed by pushing down a firm stylet within the catheter; whereby the solution is forced out of about a dozen minute apertures near the end of the instrument. This mode of applying the caustic has the advantage of being safer and more manageable than by the *porte-caustique*. It is highly commended by Mr. Erichsen, who uses a solution of the strength generally, of one drachm of the nitrate to an ounce of water. In applying either of these instruments, the prostatic urethra is known to be reached; by the distance to which the shaft has passed, and by feeling with the finger in the rectum, also by the sensitiveness of the part. Considerable irritation, pain, and bloody or mucopurulent discharge, follow the operation; with perhaps an aggravation of the nocturnal emissions. These subsiding in a few days, the cure may be complete; or the caustic may have to be re-applied when the urethra can bear it, at intervals of a week or two; and sometimes no good results from the treatment.

*Impotence* signifies an absence, loss, or premature decay, of sexual and procreative power; with generally a corresponding negation of sexual desire. The seminal secretion may be absent; a condition known as *Asperma*, and which contrasts with that of Seminal Flux. But as in that condition, any slight secretion is often thin and spurious; not containing spermatozoa or only in scanty quantity.

It is highly important not to mistake the nature of the *prostatic* secretion; which may be discharged from the urethra as a tenacious fluid, like white-of-egg, in small quantity, and following the urine, or expelled during defæcation, especially when accompanied by a straining effort. Such discharge is quite consistent with an absence of *Spermatorrhœa*,—the presence of impotence.

The *cause* of impotence may be some congenital, or acquired, deficiency, of, or affecting, the genital organs.

*Congenital* impotency is sometimes a cerebral imperfection, as occurring in idiots; or from a want of that concurrence of forces which is requisite for the complicated process of generation. This constitutional impotence is not necessarily associated with any discoverable imperfection in the organs, or any obvious defect of bodily formation. It may, indeed, be associated with full intellectual vigour; and with a physique endowed with great muscular power, developed also by athletic exercises. But more often, the external indications of virility are defective when sexual power is wanting.

*Acquired* impotence may be the result of prolonged sexual excesses, or of habitual physical exertion; in either way exhausting the nervous energy. Occasionally, it follows injuries of the head, and usually when the patient is convalescent. Wasting of the testicles may be the first announcement of generative failure; and this may be persistent, or the sexual power gradually returns.

The *Treatment* of Impotence must have reference to its various causative conditions ; consequently, it is often incurable.

NEURALGIA OF THE TESTICLE.—This affection of the testis, resembles neuralgia as occurring in other parts. The pain varies in character and severity ; being sometimes dull and aching, or darting and so acute as to make the patient roll on the floor in sweating agony. Often the pain is paroxysmal.

Various causes, local and constitutional, may give rise to this suffering ; any source of irritation in an adjacent organ, as stone in the bladder, kidney or ureter ; or disease of any part of the urinary apparatus ; varicocele ; gastric or hepatic irritation ; or it may arise from a depressed state of the general health, especially as the consequence of malarious influence, and then the pain usually recurs periodically. The testicle itself is generally healthy in its structure.

*Treatment* of a curative character implies the discovery and removal of the cause in operation, and these requisites cannot always be fulfilled. Tonics, especially quinine and iron, are remedial ; particularly in the periodic form of the neuralgic affection. The hypodermic, or perhaps the testicular, injection of morphia, might be worthy of trial.

Ought castration ever to be performed as a last resource to relieve pain, or in compliance with the urgent request of the patient ? The question is a serious one, inasmuch as it relates to the removal of an organ, not structurally diseased and important in itself ; and which may almost at any moment cease to afflict the patient. But this question should be considered, with reference to the probability of removing the cause of neuralgia, persistence of this painful affection undermining the general health, and with regard to the urgency of the patient's request when the nature of the case is explained to him, in an intermission of pain. Sir A. Cooper was induced by the latter consideration to perform castration in three cases of the kind ; and other Surgeons have deemed it advisable to do the same. Yet the operation is justifiable only in rare and exceptional cases.

MAL-POSITION OF THE TESTICLE.—In the fœtus, the testes are contained within the abdomen, in the lumbar region ; whence they gradually descend through the inguinal canal into the scrotum, a change of situation which is usually completed before birth. But, by an arrest of development, this descent of the testis may be retarded until after birth, and it may then never take place completely. The descent of this organ is delayed till a few months, or a year, after birth, in about 1 infant in 5. It occurred at a later period in many cases which came under Sir A. Cooper's observation ; the testis descending at from one to seventeen years, or even twenty-one years. Complete descent fails to take place in about 1 person in 1000 ; and then the testis may be permanently retained in the abdominal cavity, or in the internal abdominal ring, or in the inguinal canal just above the external abdominal ring. The right or the left testis is nearly equally liable to these mal-positions ; and rarely it happens with both testicles.

The causes of any such failure of descent would seem to be a deficiency in the force, whether it be the contraction of the fibres of the gubernaculum or some other force, whereby the descent of the organ is effected ; or sometimes, an impediment to the process ; as an imperfect development of the mesorchium, or adhesion to one of the viscera or to the abdominal wall, consequent on intra-uterine peritonitis ; imperfect patency of one of

the inguinal rings, or some obstacle in the inguinal canal. Shortness of the vas deferens or of the spermatic vessels, may also be regarded as a cause of retention ; though the cord is often tortuous or convoluted.

The condition of the retained testis, as to its *structure* and *function*, is variable. It has been found of full size, rarely ; generally, it is imperfectly developed, being smaller than natural, and its gland-tissue remaining immature as in the infantile organ. Or, it may be atrophied, and have undergone fibrous or fatty degeneration, obliterating any trace of gland-structure. Functionally, the organ is incompetent. This want of secretory power for the production of spermatozoa, is of little consequence when the other testicle has descended and is healthy ; the one organ being quite sufficient for generation. But when both organs are retained, the procreative power will usually be completely wanting ; the individual is absolutely impotent. He may have full sexual desire, power of erection, and emissions during connexion ; but the spurious seminal fluid contains no spermatozoa, and has no impregnating influence.

*Diseases of retained testicle.*—The organ is liable to *inflammation*, and to *malignant disease* ; and orchitis is especially liable to occur when the testis is lodged in the inguinal canal, the inflammation arising from gonorrhœa or from injury. The diagnosis between a retained testis in that situation, and inguinal hernia, or even bubo, must be determined by reference to the symptoms of these conditions. Mistakes have been made by eminent Surgeons, and Ricord nearly mistook an inflamed testis for a bubo. *Congenital hernia* not unfrequently accompanies and complicates undescended testis in the inguinal canal. The testis may be unable to bear the pressure of the truss requisite to prevent the descent of the hernia ; while in an operation some difficulty is often experienced, owing to adhesion of the gland and bowel.

*Mis-descent* of the testicle has been known to occur ; the organ descending and escaping into the perineum near the anus, or into the pelvis ; or through the crural ring and saphenous opening, thence upwards upon the abdomen, and simulating crural hernia, or lodging behind the fascia in the upper and inner part of the thigh.

*Inversion* of an undescended testis is occasionally met with ; the vas deferens and epididymis presenting forwards, and the body of the organ looking backwards. The diagnosis of any diseased condition is then rendered more difficult. If hydrocele co-exists, the fluid swelling will be situated behind the testicle.

#### DISEASES OF THE VESICULÆ SEMINALES.

These two oblong, sacculated receptacles for semen lie at the base of the bladder, and converge from behind forwards to the base of the prostate ; the vasa deferentia come forwards between them to that gland, and each vas there joins with the opening of the corresponding seminal vesicle, to form the common ejaculatory ducts. Thus situated, and connected, the seminal vesicles are not uncommonly diseased in company with the testicles, or sometimes independently of those organs ; and these diseases may induce or aggravate disease of the bladder, and less frequently, of the rectum.

The seminal vesicles are subject to *inflammation*, arising independently or in consequence of gonorrhœa ; and they are liable to *chronic* enlargement, especially of a scrofulous character ; and to *malignant* disease.

*Diagnosis* is much facilitated by the situation of these bodies, as they lie within reach of the finger passed into the rectum.

*Treatment* must be conducted on ordinary principles.

## CHAPTER LXIII.

## INJURIES AND DISEASES OF THE FEMALE GENITAL ORGANS.

A LIMITED notice only can be taken of some of the Diseases which affecting, or specially pertaining to, the Female Genital Organs, come under the observation of the general Surgeon; and principally with regard to the operative procedures requisite for their cure.

These *Diseases* relate to; (1) the External Organs, or the *Vulva*, in its several parts, and the *Vagina*; with which may be conveniently associated, the *Perineum*; (2) the *Uterus*, and Fallopian Tubes; (3) the *Ovaries*.

The External Organs are also liable to *Injuries*; in the form of Wounds of the Vulva, or of the Vagina, and Laceration of the Perineum; or the introduction of Foreign Bodies.

(1) EXTERNAL ORGANS.—WOUNDS OF THE VULVA, present nothing peculiar, excepting the proneness to copious hæmorrhage, owing to the natural vascularity of the labia, nymphæ, and clitoris. But the tendency to primary union is remarkable. The treatment, therefore, is by suture and simple dressing.

Wounds of the *Vagina* are even more rare than of the vulva. In Mr. Erichsen's practice, a remarkable case happened; a cedar pencil, five inches long and cut to a point, had been forced up through the posterior wall of the vagina of a young woman into the abdominal cavity, and there it transfixed two coils of the small intestine. After a sojourn of eight months, it was extracted by an incision through the anterior abdominal wall, midway between the umbilicus and Poupart's ligament, where its point was engaged in the fascia transversalis. It had occasioned repeated attacks of peritonitis, and after its extraction, death resulted from that cause.

LACERATION OF THE PERINEUM.—This injury happens occasionally during parturition; in consequence of the large size of the fœtal head, or from rigidity of the perineum; or sometimes, by what, I believe, may be fairly designated the unskilful use of the hand in the vagina, or of instruments. During parturition, laceration or rupture of the perineum occurs in the passage of the fœtal head. It varies considerably in its extent and consequence. Perineal laceration may be regarded as of four degrees; that which is limited to the anterior edge of the perineum; that which extends backwards through the whole length of the perineum to the sphincter ani; or perhaps, involving this muscle; and occasionally extending into the recto-vaginal septum. A combination of laceration and sloughing is sometimes met with; the perineum being torn through, and the recto-vaginal septum destroyed by sloughing, from prolonged impaction of the fœtal head. The fissure, directly resulting from laceration and increased by loss of the septal substance, may be complicated also by the subsequent formation of dense bands of imperfect cicatrix; thus presenting the most difficult form of lesion in regard to treatment.

The *consequences* of laceration depend upon its extent. Whenever it passes beyond the anterior margin of the perineum, and especially when it involves the sphincter ani and perhaps the septum; there will be a

tendency to prolapsus of the uterus and bladder, of the rectal mucous membrane, or of all these parts; and with the latter condition, as depending on the sphincter having given way, there will also be inability to retain the *fæces*,—incontinence of *fæces*.

*Treatment*.—Operative interference is absolutely necessary in all degrees of perineal laceration, except that of a slight rent in the front margin of the perineum. This will, generally, heal by rest, and cleanliness, with perhaps an occasional touch with nitrate of silver.

The *operation* in each of the other degrees of further laceration, is essentially the same; a plastic procedure, which consists in freely paring the edges of the fissure, and bringing them together by quilled sutures, to procure union by adhesion. *Prior* to operation, the patient's general health should be brought into the best possible state, and any source of local irritation removed; as these two conditions will mainly determine a successful result. The operation is then performed as follows.—The bowels having been thoroughly emptied, chloroform is administered, and the patient placed in a lithotomy position; a duck-billed speculum is passed into the vagina, so as to elevate the upper floor, and thoroughly expose the perineal fissure. This must then be freely pared throughout its depth and extent, on either side; thus to prepare two raw surfaces, together of nearly a horse-shoe shape. The width of the raw surface averages about an inch. Unless the surface be thoroughly pared, so as to form a good thick cushion instead of only a thin cutaneous support, the tendency to prolapsus will continue; and any point of undenuded surface will probably be followed by the establishment of a fistulous opening. Hemorrhage is often rather free, and the fissure should not be brought together until this has ceased. Ice is the best styptic. Division of the sphincter ani, on each side of the coccyx, is recommended by Mr. Baker Brown, in order that its action shall be paralysed and all tension of the part be overcome. This additional feature in the operation is necessary, or at least advisable, when the laceration passes high up into the recto-vaginal septum. The parts having ceased to bleed, and coming freely together into *easy* apposition; the quilled sutures are applied at as many points as may be necessary to bring the surfaces into one line of union. For this purpose, two pieces of bougie may be used; or two quills, rods of glass, or perforated metal bars. Fine whipcord is the best material for the sutures. By the thickness of the raw surfaces, and the firm support of the lateral rods, the superficial edges of the fissure are often seen to be everted. In concluding the operation, therefore, it may be advisable to bring the *edges* together with a few points of ordinary interrupted suture; using metallic wire in preference to fine silk.

*After-treatment* is very important. It consists in preventing any intestinal action for ten or twelve days, by keeping the patient sufficiently under the influence of opium; and averting any dribbling of urine over the raw edges, by retaining a catheter in the bladder, furnished with a long india-rubber tube to carry off the urine free of the person. Scrupulous cleanliness of the parts is absolutely necessary. The strength must be maintained by abundant fluid nourishment. The sutures should not be removed for a week; and rest in the recumbent posture be still continued for two or three weeks longer lest the recently united parts might yield.

Prolapsus, when effectually cured by the operation, is previously much ameliorated by this prolonged recumbency; the turgid and ulcerated os-

uteri recovers a healthy state, and the relaxed uterine ligaments have time to regain their tension.

The *results* of this operation require further investigation. But, the extent of laceration, and sometimes loss of substance, materially affect the issue. When the laceration involves the sphincter ani, and is consequently attended with incontinence of feces; an operation for the restoration of the perineum will effectually afford the support necessary for control over defæcation. But the lesser evil consequence of such laceration—prolapsus, will be less certainly remedied. It may be cured temporarily, the prolapsus subsequently returning. In 10 cases on which Mr. Jonathan Hutchinson operated; two or three of the patients continued to suffer from prolapsus, although in a lesser degree; three remained permanently cured. In one of these successful results, the patient was an elderly woman, and who had suffered from most distressing prolapsus. *Failures* of the operation sometimes occur; more often as the result of extensive laceration, and perhaps loss of substance. No union was obtained in one of Mr. Hutchinson's cases. I have also experienced in one case, partial non-union. Recto-vaginal fistula is an occasional result, principally from incompleteness of the operation itself.

FOREIGN BODIES IN THE VAGINA.—Various kinds of foreign bodies may be introduced into the vagina; accidentally, or intentionally, and in the latter case occasionally, with malicious intent. Thus, by a fall, the spike of an iron railing has been known to enter the vagina; in the Museum of the Royal College of Surgeons, there is a glass tumbler which a woman had thrust into her vagina, for some purpose best known to herself; and I have extracted a piece of swollen sponge from the os uteri, which a young woman had passed up her vagina, with the view of preventing the liability to conception from sexual intercourse.

• The danger arising from the introduction of foreign bodies into the vagina, will depend upon their nature, the amount of damage done, and the period of impaction. A hard, rough body, forcibly thrust up the passage, is often productive of copious *hæmorrhage*, especially by laceration of the labia externally. A pointed body, may *perforate* the vagina, as in Mr. Erichsen's case of punctured wound already mentioned. The continued impaction of a foreign body gives rise to *vaginitis* and discharge, requiring appropriate treatment, even when the substance has been removed.

DISEASES OF THE EXTERNAL GENITALS.—HYPERTROPHY OF THE LABIA, OR OF THE CLITORIS.—These parts are liable to enlargement, of a fibro-cellular character; sometimes forming an apparently distinct outgrowth. This hypertrophy, or tumour, seems to be the result of prolonged irritation, in connexion with some fissure of the part, or from morbid vaginal discharge. A fibro-cellular out-growth of the clitoris, which had attained to the size of a very large cocoa-nut and weighed thirty ounces, was removed by Dr. A. Marsden at the Royal Free Hospital. I gave a short description of the growth in *The Lancet*, August, 1857.

*Excision* is the only remedy for these conditions. *Hæmorrhage* is often profuse, the blood coming from a number of small vessels. A good precaution, therefore, is to transfix the base of the mass by means of hare-lip pins and twisted sutures, before using the knife.

CONDYLOMATA OR VERRUCÆ are of common occurrence, in consequence of prolonged irritation from syphilitic or gonorrhœal discharge, and uncleanness. A large cauliflower mass is at length formed. Its removal can

sometimes be effected, like warts of the prepuce in males, by dusting the part with a powder consisting of equal proportions of pulverized savine and copper. Excision, however, must generally be resorted to when the mass is considerable; and this is accomplished most readily with scissors curved on the flat.

*Abscess of the labium* occurs, not unfrequently, in consequence of some injury to the part in sexual intercourse. It is most liable to happen soon after marriage, when the parts are as yet unaccustomed to attrition; and in prostitutes, from the contingencies of promiscuous intercourse. The abscess seems to arise by rupture of one of the veins in the labium; and when it bursts on the inner side, after the lapse of perhaps only a few days, or is laid open by incision, it discharges a mixture of venous blood and fetid pus.

CYSTIC TUMOURS, are occasionally met with in the subcutaneous cellular tissue of the external genitals. They occur in two situations; either about an inch and a half within the vulva, a little below the middle of one or other side of the vagina, and as the result of enlargement of Cowper's glands; or, in the cellular texture of the labia, where the cyst attains to a larger size—that of a chestnut or even a small orange, and resulting from the enlargement of a mucous follicle. In both situations, the cysts contain a glairy fluid, perhaps tinged with blood from any slight injury of the part.

*Diagnosis.*—Cysts may be distinguished from *abscess*, by the absence of inflammatory symptoms, or of such symptoms in the history of origin. A cyst may become the seat of inflammation and be converted into an abscess. The diagnosis will then be most difficult or impossible, unless the patient's own evidence can be trusted as to the previously distinct formation of a cystic swelling. From *inguinal hernia* descending into the *labium*, a cyst is distinguished by its incompressibility, irreducibility, and the absence of impulse on coughing. Puncture of the swelling may of course be resorted to in any doubtful case, when the possibility of hernia is excluded from the diagnosis.

*Treatment.*—Obliteration of the cyst can not unfrequently be effected by a free incision, and the introduction of a strip of lint to provoke suppurative granulation from the bottom of the cavity. Excision is a more speedy cure; but the dissection, easy in itself, is somewhat embarrassed by the free hemorrhage from the vascular texture of the labium. This may be arrested by pressure with a compress and T bandage.

EPITHELIAL CANCER, is not very uncommon in the labia and vagina. It presents the same characters as in other parts. An irregular, undermined, indurated margin, an unhealthy gray surface, and a tendency to the production of warty granulations, are its most distinctive appearances. It may commence in, or extend into and up, the vagina; converting this passage into a hard, solid, open tube, having a tuberculated surface, of an ash-gray colour. This state of the vagina was well marked in a patient under my care at the Hospital. The inguinal glands speedily become infected. Middle-age is most predisposed to this affection.

*Treatment.*—The disease may be removed by excision, or by caustic; and any affected glands must also be extirpated. In the case just referred to, I freely cauterized the interior of the vagina with strong nitric acid, but only with temporary benefit. A speedy recurrence of the disease is the, perhaps, invariable result of any interference.

*Rodent ulcer* is very rarely met with on the female genitals. It may

be distinguished from epithelial cancer, by the absence of warty growth, by its slow progress, and by the freedom of the glands from infection.

This disease is amenable to excision.

**VASCULAR OR ERECTILE TUMOURS**, not uncommonly grow near, or just within, the meatus urinarius. Such tumours are broad-based or pedunculated, of small size, red and disposed to bleed, sensitive or painful. Pain in micturition, and in sexual intercourse, with occasional bleeding, may lead to an examination, and then the source of irritation is discovered.

*Treatment*.—Complete removal of the growth is the only cure, and this may be effected by excision with curved scissors, ligature, or cautery. The sub-mucous base must be removed with the growth; it will therefore be necessary to thoroughly expose the part for operation, and it may be desirable to place the patient under the influence of chloroform.

**CLOSURE OF THE LABIA, OR OF THE VAGINA**.—As the result of malformation, it not unfrequently happens, that the *Labia* are adherent, leaving perhaps a pin-hole opening for the trickling escape of urine. This defect is usually discovered in infancy, when the adhesion can be easily separated.

*Treatment* consists in simply running a probe between the labia, and then inserting a strip of oiled lint to prevent re-union. The cure is generally permanent; it was so in a recent case brought to me for relief.

Closure of the *Vagina*, as the result of malformation or sometimes of adhesive inflammation in early life, is a defect less apt to attract attention, and seldom discovered until the period of menstruation. Amenorrhœa then arising from accumulated retention of the menstrual secretion, this is attended with a sense of bearing-down weight in the perineum, which suggests the necessity for an examination.

*Treatment*, here also, consists, in opening the vagina, and tearing asunder the adherent walls with the finger or the handle of a scalpel; and then introducing a pledget of oiled lint, until the surfaces have healed separately.

*Imperforate Hymen* is another occasion of occluded vagina. This defect also will probably remain undiscovered until puberty. The accumulated retention of menstrual fluid at length causes distension and protrusion of the imperforate and thickened hymen beyond the vulva, with a bearing-down weight; while, an elastic fluctuating tumour can sometimes be felt above the pubes or in the iliac fossa.

*Treatment*.—An aperture must be made in the hymen; and this may be done by puncture with a trocar, and then enlarging the opening with a probe-pointed bistoury; or by making a free crucial incision. Complete removal of the hymen by dissection, has been recommended by Mr. Baker Brown: but this extreme procedure seems unnecessary for the functional freedom of the vagina, and indeed might be followed by cicatricial stricture. In either mode of freeing the passage, the urethra must be carefully avoided; a precaution less easily observed when “the hymen is removed entire by a circular incision.” An opening having been made, the retained menstrual fluid is discharged, often in a very large quantity and of a very offensive odour. The relief thus afforded is immediate. But the danger and fatality of this simple operative procedure is considerable. Peritonitis often ensues; not, of a puerperal or contagious character, as was formerly suggested by Dr Blundell and others; but apparently in consequence of some of the menstrual fluid finding its way

upwards through the free extremity of the Fallopian tube into the cavity of the peritoneum, or by rupture of the tube which, with the uterus, had previously undergone dilatation from retrogressive distension with the accumulated fluid. That these two events should occur after the relief of tension by operation, is remarkable; yet they seem to be established by the observations of Bernutz, Goupil, and Jonathan Hutchinson.

*Partial imperforate hymen* is occasionally met with. This condition, however, is no barrier to marriage, or to impregnation; or even to parturition, the hymen rupturing, usually, under pressure of the foetal head.

Incision will be desirable to free the patient from any unhappy matrimonial restraint.

**RECTAL AND VAGINAL FISTULÆ.**—Fistulous openings may exist in the Female Organs; between the rectum and vagina,—*Recto-Vaginal Fistula*; or between the bladder and vagina,—*Vesico-Vaginal Fistula*. These Fistulæ, and their modifications, have already been described, as thus designated, in previous parts of this work.

**PROLAPSUS VAGINÆ.**—A falling-down of the vagina is liable to occur; either in its anterior wall, with protrusion of the bladder, constituting *Cystocele*; or, in its posterior wall, forming *Rectocele*. These conditions present the characteristic appearance of the rugous walls of the vagina, and are thus distinguished from prolapsus of the uterus, in which the os uteri descends as the most prominent part of the protrusion. The sense of bearing-down, and constant vaginal discharge—with the vesical irritability in cystocele—usually compel the patient to seek relief.

*Treatment* may be palliative or curative. The *former* consists in returning the protrusion, and supporting it by the introduction of a properly-shaped pessary; the globular boxwood pessary being, I believe, most suitable. A much larger one can be conveniently worn than would seem requisite, owing to the relaxation and enlargement of the vagina above the entrance, as the consequence of prolapsus. *Curative* treatment consists in having recourse to a plastic operation; by paring off a strip of mucous membrane from below the meatus on one side round to the same point on the other side, and uniting the raw surfaces by suture. The width and length of the strip should vary according to the degree of prolapsus; the object being to sufficiently narrow the canal for the permanent support of the protrusion. As after other plastic procedures relating to these parts, the bowels should be confined by opium, and scrupulous attention paid to cleanliness; a catheter communicating with an india-rubber tube is retained in the bladder to carry off the urine.

**TUMOURS.**—The vagina may be the seat of tumours, springing from its walls. *Mucous polypi*, and *cystic* growths, are here met with. Their relations must be carefully made out before resorting to any operation. When the tumour grows from the posterior wall of the vagina, rectal examination will determine this question.

*Removal* of these tumours can be effected by excision or ligature.

(2) THE UTERUS is subject to various Displacements; and to the formation of Tumours, benign and malignant.

*Displacements* comprise: various alterations in the direction of the axis of the uterus,—*Anteversion*, *Retroversion*, *Latero-version*, right or left; corresponding forms of *Flexion* or bending of the uterus upon itself; and *Prolapsus*, which, when incomplete, is distinguished as *Procidentia*.

The *causes* of these displacements are mostly represented by any occasion of increased weight of the organ, so situated as to produce the particular form of displacement.

*Treatment* must be directed to the removal of whatever cause may be in operation. When the displacement is due to inflammatory turgescence, this cause will obviously be more capable of removal, than when it depends on some structural enlargement. Leeches, astringent injections, cold hip-baths, and the recumbent position; are most effectual in reducing vascular engorgement. *Mechanical* means may then be resorted to with advantage, and they are the only remedial measures available in displacements depending on structural enlargements. These means consist in returning the prolapsus, and then supporting it in position by the introduction up the vagina of a properly-shaped pessary. The perforated cup-shaped pessary is generally the most suitable form; it slopes off into a hollow stem, and the stem moves externally on an ivory ball-and-socket joint, with an oval shield over the entrance to the vagina. The shield is enclosed in a close-fitting linen case, furnished with abdominal tapes, whereby the pessary is retained in position as the uterine support; the hollow stem draining off uterine discharge; and the ball-and-socket joint at the vulva allowing of free motion in every direction, without displacing the uterine support. I have used this apparatus in three otherwise uncontrollable cases of complete prolapsus uteri, the womb having descended beyond the vulva so as to hang between the thighs. In one of these cases, the patient was a young unmarried woman, who had never borne a child or been pregnant. In all, the relief afforded was most satisfactory, and a life of previous misery became enjoyable; the patients walking about with ease and comfort, and entering into society without restraint.

Displacements by version or flexion of the uterus may be rectified by passing the uterine sound into its cavity.

**TUMOURS.**—*Fibrous* tumour is of not uncommon occurrence. It may occupy any portion of the uterus; embedded in the uterine wall, projecting into the abdominal cavity, or pedunculated in the cavity of the uterus or even protruding into the vagina, as a fibrous polypus. The tumour is slow-growing, but may attain to a large size, weighing several pounds. In the two first named situations, fibrous tumour may occasion little inconvenience, and its presence remain unsuspected during life; but as a fibrous polypus, the growth may entail constant suffering and endanger life.

The age of production, or at least of discovery of uterine fibrous tumour, is usually between thirty and forty.

*Treatment.*—Removal of the tumour cannot be effected by absorption; and any medicinal treatment for this purpose, whether by the administration of iodine or mercury internally, or by the introduction of these agents into the vagina, will be of little or no avail.

On the other hand, the propriety of *operative* interference must be well considered.

The slight connexion, vascular or fibrous, between an embedded fibrous tumour and the uterine substance, is a structural condition favourable to removal of the mass by "Enucleation." When also the tumour is pedunculated, and presents into the uterine or vaginal cavity, its removal may be effected by Ligature. But the difficulty and danger of the former mode of operation, are serious considerations. The necessity for such operation should, therefore, always be determined by the presence and

urgency of symptoms. And the necessity thence arising will be absent, in proportion as the tumour is embedded, or projects into the abdomen.

*Enucleation* may have one of two objects in view; direct removal of the tumour at the time,—*primary* enucleation; or, the disturbance only of the relations of the tumour, so as to induce gangrene,—*secondary* enucleation.

The following conclusions, as to the relative propriety of these methods of operation, are offered for general guidance, by Mr. Jonathan Hutchinson, after much careful study of the subject:—(1) That Surgical interference with interstitial fibrous tumours of the uterus is always attended with considerable risk, and ought not to be practised except under circumstances of urgency, or when the position of the growth is peculiarly tempting. (2) That when the tumour is not of very large size, and is already partially extruded, the operation is rendered comparatively free of danger, and ought to be performed at once. (3) That when the tumour is wholly embedded, and even when of large size, enucleation is yet warrantable, if there be perilous hæmorrhage. (4) That primary enucleation, where at all easily practicable, is much preferable to the secondary method. (5) That where the tumour is very large, or where found after the incisions to be firmly united to its capsule, the secondary plan is preferable. (6) That whichever plan is adopted, the first incision should, excepting under unusual circumstances, be made from within the cavity of the cervix, and should be as free as possible. (7) That the danger of hæmorrhage from this incision is very slight. (8) That as much should be done as practicable at the first operation in freeing the tumour from its cyst. Thus if the adhesions be found more loose than had been expected, a primary enucleation may be completed where the slower plan had been proposed. (9) That in secondary enucleation, the Surgeon need not be anxious about the removal of the tumour *en masse*, but may confidently expect, that if sloughing be induced in its lower part, the piecemeal disintegration and death of the whole will follow.

*Operation of Enucleation.*—This mode of removing uterine fibrous tumours, has been practised chiefly within the last twenty years, and principally by Sir James Simpson, Mr. Teale, and Mr. Baker Brown, among British Surgeons. In America, Dr. Atlee has advocated and practised it in several cases; and in France, the operation has been performed by Lisfranc, Jarjavay, Amussat, and Maisonneuve. Mr. Jonathan Hutchinson has carefully analysed the experience derived from 39 recorded cases (*Medical Times and Gazette*, 1857), and he gives the following directions for performing the operation of *primary* enucleation:—1st. To have the tumour well depressed into the pelvis by an assistant. 2nd. To let the first incisions be very free, and pass deeply into the tumour, thus not only completely dividing its capsule, but facilitating its bisection, should that afterwards be found requisite. The scalpel should be passed into the uterine cavity, and then the edge turned on to the tumour, and the incision made downwards, and either forwards or backwards, according as the mass may occupy the anterior or the posterior wall. No important hæmorrhage attends this incision, and the whole substance of the tumour intervenes between the knife and peritoneum. 3rd. The capsule of the tumour having been opened, its separation should be effected by the finger, or if necessary, by blunt-pointed curved scissors, the finger being used as a director. The instruments here requisite occasionally; are curved scissors of various shapes and sizes, one of which should be very long, strong and

large vulsellæ, a blunt hook, a spatula, a scoop, and a pair of small mid-wifery forceps; also a strong whipcord ligature and the appliances for its use, should be at hand in case of need. 4th. Having separated the tumour from its cyst-wall, its lower part is seized and drawn down, so as to invert the uterus sufficiently to make room for removal of the tumour. Traction must be made in the axes of the pelvis, and steadily, not by jerks. 5th. Eversion having been accomplished, an examination should be made with the finger *per rectum*, in order to ascertain the relative position of the parts, and then the remaining attachments of the tumour must be cautiously separated. The utmost care must be taken not to cut into an inverted pouch of peritoneum. 6th. If the tumour be a large one, it may be found convenient, before drawing it down, to cut away a portion or portions and thus diminish its bulk. 7th. The operation complete, the inverted uterus must be returned; if necessary, a sponge-plug should be introduced, and a full dose of opium be given. 8th. Ice, ergot of rye, and diffusible stimuli must be resorted to, or not, according to circumstances.

*Secondary* enucleation, by inducing gangrene, requires no particular directions for its performance; the object being to disturb the relations of the tumour and inflict such injury on it as may lead to sloughing, and thence enucleation,—an occasionally natural mode of cure. By this method, several operations, after intervals of time, are usually requisite. Ergot should be administered, to maintain vigorous uterine action; the patient's strength sustained, and sloughs removed as soon as formed. In case of great exhaustion, and threatened pelvic inflammation, the internal administration of turpentine is of great value.

The *comparative results* of these two methods of enucleation may be thus stated; the primary method is more immediately serious, the secondary method entails a subsequent and protracted risk. The gross risk of the two modes is almost equal; but in either way, about two-thirds of the cases of enucleation end in recovery.

**UTERINE POLYPI.**—Various kinds and shapes of polypoid growths are liable to spring from the walls of the uterine cavity. (*a*) a sessile soft growth of small size, containing one or more mucous cysts, which consist of enlarged uterine follicles and hypertrophied cellular texture. Occasionally, pedunculated cysts attached to the cervix uteri: (*b*) a pedunculated growth of small size,—from that of a bean to a nut, soft, vascular, and often multiple, consisting of pendulous mucous membrane, and analogous to nasal mucous polypus; (*c*) a growth of finer texture and larger size,—a nut to an egg, more or less pedunculated, and consisting of mucous membrane, with a large excess of cellular tissue; (*d*) a much firmer growth than any of the preceding, and usually of much larger size, pedunculated or sessile, its attachment usually uterine,—the common fibrous polypus; (*e*) recurrent fibroid polypus; (*f*) malignant polypus.

*Signs.*—Hæmorrhage from the vagina is the most common symptom; occurring irregularly, sometimes copiously, and continuing for a long period, unrestrained by any ordinary treatment. The amount and frequency of the hæmorrhage often diminishes when the polypus escapes from the grasp of the cervix; and usually it lessens in proportion as the peduncle becomes longer and thinner. Leucorrhæal discharge is a less characteristic symptom. But, pain of a bearing-down character is experienced in all forms of uterine polypi. Examination *per vaginam* should be at once resorted to, by means of the speculum and digital exploration;

and then one or other of the above described polypoid growths will probably be discovered, protruding into the vagina.

*Diagnosis.*—Severity of pain is tolerably characteristic of *malignant* polypoid growth and hæmorrhage is usually more abundant. The period of life most liable to the *benign* forms of polypi is that of menstrual activity, rather than of very early or later life; but no age is exempt. Vaginal examination may determine the diagnosis.

*Treatment.*—Benign polypi admit of removal, by scissors, torsion, ligature, or écraseur. The risk of hæmorrhage should mainly determine the selection of either method of operation. But when the peduncle is long and thin; the best plan is to snip it through with scissors, or twist it with forceps until it gives way. Ligature may be applied by means of a noose of whipcord passed through Gooch's double canula; the ends of the cord are gradually tightened, and thus the ligature cuts its way through the peduncle in the course of a few days. During that time, however, a decomposing, fetid mass occupies the vagina, requiring the use of chlorinated injections to wash away the sloughing discharge. The uterine portion of peduncle gradually undergoes absorption.

**CANCER OF THE UTERUS.**—All forms of cancer may affect the uterus; either primarily, as being the seat of the disease; or secondarily, by invasion from other organs. Thus, we recognise scirrhus, encephaloid, and rarely colloid cancer of the uterus; also epithelial cancer and the so-called cauliflower excrescence. But it is only when seated in the os uteri, and at an early period of the disease, that uterine cancer is amenable to Surgical treatment.

*Signs.*—Pain and hæmorrhage, in a greater degree than as arising from any form of benign uterine tumour, are tolerably characteristic of cancer. But vaginal examination must always be had recourse to, and perhaps confirmed by microscopic examination of a small portion of the tumour or of the discharge from its surface. The disease usually commences in the form of a scirrhus tubercle of the cervix; which proceeds to ulceration, having the ordinary appearances of a cancerous ulcer, accompanied with offensive, muco-purulent and bloody discharge. Constitutional cachexia speedily ensues.

The *diagnosis* from syphilitic ulceration of the os uteri is often difficult, in an early stage of cancerous ulceration. A greater tendency of the latter to bleed, its warty and thickened edges and fetid discharge, are the most distinctive symptoms; affirmed or negated by microscopic examination.

As to the different species of malignant disease; the kind of cancer present is far less important than its extent.

*Treatment.*—When the disease is limited to the lips of the os uteri, and if the organ itself be unenlarged and freely moveable; any kind of cancer may be removed by excision, or caustic.

*Excision* of cancerous ulcer of the os uteri was originally performed by Oslander of Göttingen, and subsequently by Lisfranc of Paris. In this country, Sir James Simpson has had the largest experience of the operation. No particular directions are necessary for its performance; the operation consisting in dilating the vagina with the duck-billed speculum, seizing and dragging down the os with forceps, and then excising the affected portion. Hæmorrhage must be restrained by the actual cautery, or by perchloride of iron. It will perhaps be desirable to retain hold of the stump by transfixing it with a wire; so that in the event of secondary hæmorrhage, the requisite applications can be made.

The *results* of this operation are uncertain, both as to its immediate risks, and the average duration of life in successful cases. Death has not unfrequently occurred from hæmorrhage, or from a peculiar collapse,—the “abdominal collapse” of Dr. Barnes. When not immediately fatal, the operation is productive of only temporary benefit,—the disease returning. But in one case, Sir James Simpson removed a large epithelial cancer, and eighteen years afterwards, the woman was still in good health and had borne several children in the interval.

*Cauterization* will be preferable, when the disease extends too deeply for excision. For this purpose, the dried sulphate of zinc may be used, as recommended by Professor Simpson; and in the form of a powder introduced through a speculum, or as a pessary of ointment. Some carbonate of soda, in the form of a pessary, should also be applied, to neutralize the zinc which is apt to run. The chloride of zinc, and potass fusa, are less convenient kinds of escharotics; but the galvanic cautery may prove serviceable.

Cure has sometimes been effected, or at least a temporary alleviation of the symptoms.

*Palliative* treatment is alone available in cases unfitted for operation, owing to a more advanced extent of disease. Pain may be mitigated by opiates, hæmorrhage restrained by styptics, and fetid discharge corrected by detergent injections of chlorinated solutions, or Condy’s fluid.

ABSENCE OF THE UTERUS, AND OVARIES.—This congenital defect occasionally co-exists with imperforate vagina; the external organs of generation, constituting the vulva, being present, and the breasts developed.

The *signs* of this defective condition are these:—The patient may have attained adult age without ever having menstruated, and then an examination is instituted. Simultaneous exploration with the finger in the vagina and rectum, will ascertain whether the uterus can be felt; and its absence is confirmed by introducing a catheter into the bladder, the finger still remaining in the rectum, to feel that these two organs are in contact, without the uterus intervening as in the natural arrangement of the parts. The point of the instrument can be felt thinly covered through the gut. Sexual desire usually exists in this abnormality. And it has happened, that by fruitless attempts at sexual intercourse, the urethral orifice has become dilated to such an extent as to admit the finger into the bladder. Coitus has even been effected into the expanded urethra, as if into the vagina; and thus the existence of the malformation has remained undiscovered.

No operation can be of any use; and any attempt to restore the vagina would necessarily open up the peritoneal cavity and have a fatal result.

(3) THE OVARIES.—TUMOURS, AND OVARIAN DROPSY. — Ovarian Tumours are of two kinds, *Solid* and *Cystic*.

*Solid* ovarian tumours may be either *Fibrous*, or *Cancerous*, most frequently colloid, and of a cystic rather than of a solid character, rarely encephaloid.

*Cystic* ovarian tumours, comprise; *simple* cysts, with fluid contents, and single or multiple; *proliferous* cysts, having colloid contents, or solid growths. These varieties of cysts are less frequently met with independently, but as associated in the same tumour; which thus presents the characters of a compound tumour. The activity of proliferous tendency is an indication of the affinity of the tumour to cancer growth.

As to the *relative frequency* of the different forms of ovarian disease, Dr. West supplies the following data:—of 60 cases, 41 recorded by Scanzoni and 19 by himself, simple cysts occurred in 15, fat cysts in 1; proliferous cysts, with cysto-sarcoma in 23; colloid cancer in 19, cancer with cyst-formation in 2.

*Dermoid* Cysts are not included in the above forms of ovarian disease. These peculiar cysts contain all the appendages of the skin; hair, teeth, &c., and fatty secretion. Both ovaries are equally liable to cystic disease. Of 75 cases collected by Dr. West,—19 of his own cases, 15 of Dr. R. Lee's, and 41 of Scanzoni's—in about one-third, both organs were affected. It is usually believed that the right ovary is more commonly affected than the left.

*Diagnosis.*—Ovarian tumours must be distinguished from other abdominal tumours:—from the gravid uterus in pregnancy, tumours of the uterus, omental tumours; ascites, hydatids, dropsy of the Fallopian tubes; enlargements of the liver, kidney, spleen, and stomach; hysterical tympanitis, faecal accumulations, distension of the bladder, abdominal and pelvic abscesses, and spinal curvature. The utmost care and caution must be taken in the diagnosis, before laying open the abdominal cavity for the removal of a supposed ovarian tumour, and then only discovering its real nature.

*Causes.*—No *period of life* is free from the liability to ovarian disease. During the whole period of sexual activity, it is of tolerably frequent occurrence; but in the latter half, or from thirty to forty-five, it is most frequent. It is very rare in childhood; and decidedly uncommon after the complete cessation of menstruation. It is relatively more common in *single* than in married women; and of the latter, a large proportion have been *sterile*, or not readily impregnated. Age and sexual condition afford little or no aid in the diagnosis of an abdominal tumour, as to its being ovarian. Sterility or feeble fecundity is an association of somewhat more significance, but the sexual functions may be quite healthy.

*Rate of growth.*—Commonly, in from *two to three* years from the commencement, or first discovery, of the tumour, it will have attained to such size as to occupy the abdomen, and produce various inconveniences as the result of pressure on the viscera. Sometimes the growth is much more rapid, and occasionally, especially in the aged, it may be much slower.

The *natural course* of ovarian tumours subsequently is less certainly known, treatment usually having been resorted to when it has become a source of serious inconvenience. But in patients under forty years, ovarian dropsy not interfered with, gradually undermines the general health; partly by functional derangements in consequence of unrelieved pressure, and partly by the demands of the tumour as a drain on the patient's strength. Thus, by pressure, the process of assimilation is interrupted, the circulation obstructed so that the legs become œdematous; the respiration embarrassed by upward displacement of the diaphragm and ribs; the patient can no longer rest in the recumbent posture, and worn out by sleepless nights and protracted suffering, death ensues at the end of one or two years from the date of abdominal inconvenience. Sometimes, intercurrent attacks of peritonitis, or of one of the cysts in the tumour, carry off the sufferer before the period of what may be called her natural release.

*Spontaneous cure* has been known to occur; either by cessation of

secretion and then progressive absorption, or by rupture of a single cyst into the peritoneal cavity, the intestine, or the vagina, and thus the subsidence of the tumour. But the former mode of cure is a very rare event; the latter has happened occasionally, yet always in a manner precarious or perilous, and has proved fatal instead of curative.

TREATMENT.—No medicinal measures, internal or topical, have any influence in curing ovarian tumours. Surgical treatment comprises:—(1) the Palliative operation of *Paracentesis* or Tapping, repeatedly performed as occasion may require; (2) Tapping, with various measures for inducing *Obliteration* of the cyst; as by injection of tincture of iodine, or by mechanical compression, or by the attempt to establish fistulæ for drawing away the re-secreted fluid; (3) *Ectirpation*, or *Ovariectomy*.

(1) *Tapping* is available only in Cystic tumour; where the cyst is single, or in multilocular tumours where one cyst greatly predominates in size. It affords temporary relief, re-secretion of the fluid rapidly taking place; and this entails a drain upon the patient's strength greater than would have occurred from continued secretion in a full cyst; it necessitates also a second tapping, and even many subsequent operations, each at progressively shorter intervals. The duration of life, under repeated tapplings, is probably shorter than when the tumour is left to itself; death usually taking place in three or four years after the first operation. The immediate risk from tapping is not inconsiderable; rapid exhaustion, or fatal peritonitis, sometimes occurs; and acute inflammation of the cyst occasionally. Puncture of an adherent coil of intestine must not be overlooked as a possible contingency. The operation is performed as for ascites, the point selected for puncture being one of absolute dulness; and this is usually in the middle line, a little below the umbilicus. Some other part of the abdominal wall may be more eligible, as in the linea semi-lunaris. A multilocular tumour may perhaps be partly emptied by introducing the trocar at different points, into its most prominent loculi.

(2) *Obliteration of the Cyst*.—*Injection* of the tincture of iodine, is an appropriate mode of effecting obliteration of an ovarian cystic tumour, when the cyst is single. But, in such case, the diagnosis from ascites must be very carefully ascertained; as the danger consequent on injecting the peritoneal cavity—the production of peritonitis, would be much greater than if ovariectomy were attempted by an error of diagnosis. Acute cyst-inflammation is another source of danger. If the tumour be multilocular, inflammation is very apt to follow in the uninjected cysts, in consequence of the adjoining source of irritation. Lastly, secondary cysts, which had been suppressed by the pressure and growth of a larger, predominating cyst, may subsequently become developed; thus converting an apparently unilocular cyst into a multilocular tumour, and rendering the operation abortive as a radical cure. The operation is performed by first tapping the tumour in the ordinary manner, and introducing a flexible catheter through the canula to draw off as much fluid as can be obtained; then from four to six ounces of the tincture should be injected and retained, or after about a quarter of an hour allowed to drain out. A diluted solution of the iodine might be preferred, as was recommended by Boinet, who originated this method of treatment; but there will always be a certain quantity of fluid remaining in the cyst, sufficient to dilute the tincture. Inflammation of the cyst with the effusion of plastic matter into the interior, soon follows the injection; and by this moderate degree of the process, a cure is effected.

*After-treatment* must, therefore, be directed to regulate the inflammation; stimulants or opiates being given according to the symptoms.

Sometimes the constitutional disturbance is considerable; a severe febrile paroxysm supervening with intense iodism, and impregnation of the urine and saliva with iodine.

The *results of Injection* have been not unfrequently successful; and it would seem to be less perilous than *ovariotomy*.

*Compression*, by means of a starch bandage applied to the abdomen, as a mode of effecting obliteration of the cyst, after tapping; is a plan of treatment which is now generally acknowledged to be at least useless.

*Fistulous channels* communicating with the interior of the cyst, through the abdominal wall, or through the vagina or rectum; is also a mode of obliteration which has fallen into almost entire disuse, as being more hazardous than *ovariotomy*. It is, moreover, a long, painful, and exhausting method; and the permanency of cure is very uncertain. This method would be applicable only where the tumour is unilocular.

(3) *OVARIOTOMY*.—Extirpation of Ovarian tumours, cystic or solid, is an operation of comparatively recent date. Suggested by Dr. William Hunter, advocated by John Bell, and first practised by Dr. McDowell in 1809, the latter an American pupil of John Bell, *Ovariotomy* is therefore unquestionably an operation of British origin; and it is to the labours of British Surgeons that its subsequent progress is chiefly due. The woman first operated on recovered, and survived for many years. Mr. Lizars of Edinburgh, attempted the first operation in Great Britain, in 1823; but the abdominal enlargement was found to be due only to obesity and tympanitis. The patient recovered. In London, the first attempt to perform *ovariotomy* was made by Dr. Granville, in 1827; the operation was abandoned on account of the extent of the adhesions. This patient also recovered. Both these operations had been done by the *long* incision, extending from the sternum to the pubes. The *short* incision, originally suggested by William Hunter, was first practised by Mr. Jeaffreson of Framlingham, in 1836; the patient recovering, and afterwards bearing children.

The first *completed* operation in *London* was performed by Mr. Benjamin Phillips, at the Marylebone Infirmary, in 1840; but the result was unsuccessful. The first *successful* case in the metropolis, fell to the lot of Mr. Walne in 1842, followed by two other successful cases in 1843. At length, in 1846, Mr. Cæsar Hawkins performed the operation successfully at St. George's Hospital; this being the first successful case by a Surgeon of any of our Metropolitan Hospitals. *Ovariotomy* has been *established* as a recognised operation in Surgery; by the labours of Dr. Clay of Manchester, who, in 1842, commenced his series of cases; by Dr. Frederic Bird, who began in 1843; by Mr. Lane, in 1844; by Mr. Baker Brown, in 1852; and by Mr. Hutchinson, in 1858; but Mr. Spencer Wells, commencing his long series of operations in 1857, has performed *Ovariotomy* in now 400 cases, and with such careful analysis and continued publication of his results, that they represent the most authentic source of knowledge on this subject.

*Conditions favourable and unfavourable for Ovariotomy, and the Selection of Cases*.—The following general conclusions are gathered from Mr. Spencer Wells' Report of his first and second hundred cases.

(1) The probable result of *Ovariotomy* can be estimated with far greater accuracy by a knowledge of the general condition of the patient.

than by the size and condition of the tumour. In other words, a large tumour, extensively adherent, in a patient whose heart and lungs, and digestive and eliminative organs are healthy, and whose mind is well regulated, may be removed with a far greater probability of success; than a small unattached cyst from a patient anæmic, whose heart is feeble, whose assimilation and elimination are imperfect, or whose mind is too readily acted upon by either exciting or depressing causes. Hence, the explanation of a commonly received erroneous belief; that the more advanced the disease the greater, and the earlier the stage of the disease the less, is the probability of recovery.

(2) Age.—Below the age of twenty, and between forty and fifty, the mortality is less than that between twenty and forty, or above fifty.

(3) Conjugal condition.—Among married and unmarried women at all ages, the mortality was nearly equal in the first 100 cases; and decidedly less among the unmarried women in the second 100 cases. As to any particular age, the data for comparative mortality are insufficient.

(4) Social condition.—In Hospital cases, the mortality is about 30·4 per cent.; in Private cases, about 30·6 per cent.; or nearly identical.

(5) Influence of Season.—In spring and summer, the mortality seems to be rather lower, than in autumn and winter; but the result of ovariectomy is not much influenced by season.

(6) Adhesions of the tumour.—Adhesions to the abdominal wall, omentum, or intestines, appear to have little, if any, influence upon the mortality; so that the importance which has been attached to the diagnosis of these adhesions before operation has been very greatly and unnecessarily exaggerated. But, adhesions within the pelvis, to the bladder or rectum, or around the brim of the pelvis, are very significant; as they may be inseparable without great and immediate danger to life, by injury to those organs, or to the iliac vessels or the ureters. The diagnosis of *such* adhesions is of the utmost importance. And the closeness of the connexion between the uterus and the ovarian tumour,—the length of the pedicle, will determine the possibility of keeping the end of the secured pedicle outside the peritoneal cavity, or the necessity for leaving it within this cavity. Mr. Duffin, in 1850, inaugurated a new era in ovariectomy; by pointing out the danger of leaving the ligatured end of the pedicle to decompose within the peritoneal cavity, and the great importance of keeping the strangulated stump outside. The probability of success is nearly *doubled* where the length of pedicle permits of this arrangement.

(7) Size of tumour, has not, by itself, appeared to affect the result; but size and solidity together, are important in so far as they affect the *length of incision* requisite for removal of the tumour. Of the 100 cases, it was necessary to carry the incision above the umbilicus in 20 patients. Of these, 9 died; a mortality of 45 per cent. In 80 cases, the incision did not extend above the umbilicus. Of these, 25 died; a mortality of 31 per cent., or 14 per cent. in favour of the short incision.

(8) Influence of Tapping.—As affecting the operation of Ovariectomy, the prior performance of Tapping has certain relations which are indicated by Mr. Spencer Wells' *third* series of 100 cases. That one or many tapplings do not considerably increase the mortality of ovariectomy. That tapping may often be a useful prelude to the operation; either by giving time for the general health to improve, or by lessening the shock when

the fluid is removed a few days or hours before removing the more solid part of an ovarian tumour. That when the siphon-trocar is used in such a manner as to prevent escape of ovarian fluid into the peritoneal cavity, and of entrance of air into the cyst, the danger of tapping is very small.

*Operation.*—The *Instruments* requisite for Ovariectomy are, scalpels, director, a large trocar and canula, or two, and elastic tube, strong vulsellum-forceps, clamp, whipcord ligatures, strong nævus-needles for carrying ligatures, hare-lip pins, and silver-wire sutures; strips of new flannel, and large fresh sponges, soaked in warm water. The room should be raised in temperature to 70° or 75° F.; and the patient remain if possible in the room after operation.

No special preparation of the patient is necessary; excepting that the bowels should have been opened by a gentle aperient of castor oil, on the day previous to, and by an enema on the morning of, operation; and the patient should be in her usual health.

Ovariectomy consists generally of the following seven steps or procedures in succession:—An incision in the middle line or linea alba between the umbilicus and pubes; introduction of the fingers or hand into the peritoneal cavity to gently explore the situation, nature, and extent of any adhesions, in order to determine the practicability of completing the operation; tapping the tumour, if cystic; cautious separation of any recent adhesions; securing the pedicle with a clamp, leaving a sufficient length free as a safeguard against slipping; division of the pedicle, at that distance from the clamp externally, and removal of the tumour; closure of the wound, leaving the stump and the clamp protruding through it externally.

In carrying out these directions, certain *particulars* must be observed, as essential to the probable success of the operation.

The patient clad in blankets, and chloroform having been administered; the bladder is emptied by a catheter, and the patient drawn to the end of the table, so that her legs shall hang down and the abdomen be fairly exposed. The Surgeon standing between the patient's legs, he makes an incision in the middle line or linea alba, commencing about two inches below the umbilicus and carried down to about four inches in length. By a few horizontal touches of the knife, the abdominal wall, which is usually much thinned, is divided, and the peritoneal cavity laid open. Care must be taken not to mistake the peritoneal membrane for the cyst-wall, and thus proceed to detach that membrane from the fascia transversalis; an error which has occurred several times. The peritoneum having been opened sufficiently to introduce the finger, it should be slightly raised from the cyst to make certain of this fact, and then laid open on the finger.

A longer, or even a shorter, incision may be requisite, according to the size of the tumour, and the situation and extent of the adhesions. But it cannot be necessary ever to have recourse to the long incision, extending from the sternum to the pubes as formerly practised. The fingers or the hand are now introduced into the peritoneal cavity, and the existence of adhesions ascertained, their situation, nature, and extent. They may be such as to determine the propriety of not completing the operation; the abdominal section would then have to be closed, and the patient removed. When, as usual, the operation is *proceeded* with; the tumour, if *cystic*, should be tapped, in order to more conveniently effect

its removal and through an abdominal aperture of smaller size, than would otherwise be requisite. A large trocar and canula (Fig. 469) is thrust into the most prominent part of the tumour, and the fluid drawn off through the canula. Especial care must be taken to prevent any of the ovarian fluid escaping, or passing from the canula, into the abdominal cavity; and a long vulcanized india-rubber tube fitted to the canula (see Fig. 469) will be the best safeguard. A little alteration of the patient's position, on to her side, and some compression of the abdomen, may prove advantageous in emptying the cyst.

If there be no adhesions, the tumour is now seized with a strong vulsellum and easily drawn out, as a bag, through the abdominal aperture; an assistant or two at the same time following up and closing the wound around the pedicle, so as to prevent any escape of the intestines, by handling the wound with strips of flannel wrung out of warm water. If there be any *adhesions*, or the tumour be *solid*, the fingers or hand must be passed into the abdominal cavity; the same precaution being taken by the assistants during this manipulation. When the adhesions are slight and situated anteriorly, they are readily separated by passing the hand round the front part of the tumour. When they are firm, deep-seated and extensive, the operation becomes proportionately difficult and perilous. Fortunately such adhesions are comparatively seldom found posteriorly, or connecting any of the abdominal viscera, except the uterus. These bands should be torn through, and very cautiously, not to injure the attached organ; any division with the knife being unsafe, on account of the liability to *hemorrhage* from the vessels which commonly exist in firm, organized adhesions. Any risk of *laceration* of the attached organ,

as intestine or liver, must, however, be especially avoided; and it will be more proper to cut across and leave the closely adherent portion of cyst-wall, than incur the danger of visceral rupture.

The *pedicle* protruding through the abdominal incision, as guarded by assistants; the Surgeon proceeds to secure it. This may be effected either by means of a clamp, or by ligature. The former is especially applicable when the pedicle is long and narrow; and various modifications in the form of the instrument have been proposed by different ovariotomists, each

Fig. 470.

rejoicing in the perfection of his own clamp. The form of clamp devised by Mr. Spencer Wells, is now generally employed. The two blades, com-

pressing the pedicle, are fixed by a screw (Fig. 470); and then the handles are detached, leaving a small, light instrument in connexion with the wound. Ligature will be more appropriate when the pedicle is short and thick, whereby the clamp would be drawn inwards to the pelvic cavity, or the uterus be drawn upwards forcibly towards the surface. The whipcord ligature seems to answer best, and it should be applied by transfixing the pedicle with a *navus*-needle armed with the ligature, and tying each portion securely. Care must be taken not to transfix any large artery or vein, the latter vessels particularly being large-sized, and thin-walled. The pedicle is now to be divided, at a sufficient distance beyond the clamp externally to prevent any risk of its slipping through, and thence of subsequent hæmorrhage. The ovarian tumour is thus detached.

*Closure of the wound*, leaving the clamped peduncle protruding, concludes the operation. This step may be accomplished either with hare-lip pins and twisted suture or by strong wire sutures: and these may be introduced through the entire abdominal wall including the peritoneum, or through its whole thickness, excluding the latter. They should be placed an inch and a half from the edge of the incision, on either side, so as to have a firm grasp; and not more than three-quarters of an inch apart. The lowest should be carried close to the peduncle, or it may be advisable to transfix it; and if the ligature be used, the ends may be fastened around a hare-lip pin transfixing the peduncle. Thus retained *in situ*, there will be no chance of any slough, or ligature, falling back into the peritoneal cavity. The pins and clamp are then to be padded with lint, and a four-tailed flannel bandage well applied over the abdomen. A warmed bed should be at hand for the reception of the patient, and any slight stimulant administered which occasion may require.

*After-treatment* is very important, and it comprises chiefly the following general directions. They have reference specially to the three sources of danger after ovariectomy; peritonitis, exhaustion, secondary hæmorrhage. To avoid any tendency to vomiting after the operation, nothing should be taken by the mouth during the first twelve hours, but a little ice, and no opium or other medicine. Milk or beef-tea should form the nourishment for several days; with wine or brandy as stimulants, and opium, according to the constitutional state of the patient. The nourishment may be administered by enemata, if the stomach continue irritable. No action of the bowels must be allowed, if possible, for ten days, the influence of opium having the advantage also of checking intestinal action; and the urine should be drawn off by a catheter two or three times a day. *Peritonitis* must be treated on ordinary principles, as in connexion with strangulated hernia. The management of the *wound* is simple. The portion of pedicle left external to the clamp may be cut off on the day following the operation, as there will then be no risk of slipping, and it is very desirable to avoid any source of decomposing matter. The clamp itself may be removed on the second or third day. The hare-lip pins should be left to the fourth or fifth day; and when they are removed, great care should be taken to support the abdomen and wound, by long and broad strips of plaster, and firm application of the flannel bandage.

The *results* of ovariectomy have been increasingly successful. Two recoveries, at least, to one death is a proportion which may fairly be expected in practised hands. Dr. Clay's table of cases, gathered from all

sources, gives us 212 recoveries to 183 deaths. But this is surpassed by the more favourable results of Mr. Spencer Wells' 400 cases, in which he has completed the operation of Ovariectomy; the last 100 having been only just brought, as I now write, before the Royal Medical and Surgical Society. He finds that the mortality lessens as experience increases. Of the first 100 cases, 34 died, and 66 recovered; of the second 100, 28 died, and 72 recovered; of the third 100, 23 died, and 77 recovered. But of this fourth series of 100 cases, only 22 died, and 78 recovered;—44 having been in hospital, and 56 in private practice. Of the former, the mortality was 31 per cent; of the latter, it was only 14 per cent. The mortality in private practice, Mr. Wells believes, may be taken as a guide to what may become the general average after ovariectomy; and he is convinced that,—including extreme cases, where the operation is performed as a forlorn hope, this average mortality may be reduced to about 10 per cent. One of the grandest triumphs of Modern Surgery.

- treatment of, 417
- united, 433
  - causes of, 435
  - effects of, 435
  - terminations of, 436
  - treatment of, 437

Fracture of calculus in bladder. *See*

## Calculus

## Fractures, special, 441

- of acetabulum, 464
- acromion, 450
- at ankle-joint, 480
- compound, 483
- of arm, 452
- calcaneum, 483
- compound, 484
- carpal bones, 463
- cartilages of ribs, 445
- clavicle, 446
  - in children, 449
  - comminuted, 443
  - compound, 447
  - on scapular side of coraco-clavicular ligament, 446
  - sternal side of ditto, 446
- coccyx, 466
- Colles', 461
- coracoid process, 450
- coronoid process, 458
- at elbow-joint, 455
- compound, 459
- excision for, 673
- of facial bones, 441

Fractures (*continued*)—

- of femur, 466
  - in attempts to reduce old dislocations, 559
  - complicating dislocated hip, 560
- lower end of, 473
  - impacted, 473
- neck of, compound, 471
  - extracapsular, 469
    - impacted, 469
    - union of, 470
  - intracapsular, 466
    - impacted, 467
    - union of, 468
- diagnosis from rheumatic arthritis, 592
- shaft of, 471
  - compound and comminuted, 474
- through trochanter, 471
- fibula, 478
- fingers, 463
- foot, 483
- forearm, 457
  - compound, 461
- humerus, 452
  - of humerus, in attempt to reduce old dislocation, 537
  - condyles of, 456
  - head of, compound, 454
    - excision for, 454
  - impacted, of surgical neck of, 453
  - lower end of, 455
  - separation of epiphysis of, 456
  - neck of, compound, 454
    - extracapsular, 453
      - impacted, 453
    - intracapsular, 453
      - impacted, 453
  - shaft of, 454
    - above deltoid, 454
    - below deltoid, 454
    - tuberosity, great, of, 453
- hyoid bone, 443
- at knee joint, 478
- of lachrymal bone, 441
- leg, 478
  - lower jaw, 443
  - malar bone, 442
  - metacarpus, 463
  - metatarsus, 483
  - nasal bones, 441
  - olecranon, 457
- patella, 474
  - compound of, 478
  - union of, 475
- pelvis, 463
  - separation of sacro-iliac articulation, 463
  - of symphysis pubis, 463
- Pott's, 481
- of radius, 461
  - lower end of, 461
  - impacted, 462
- of radius and ulna, shafts of, 460

Fractures (*continued*)—

- of ribs, 444
  - compound, 444
  - penetration of pleura and lung, 445
  - situation of, 444
- sacrum, 465
- scapula, 449
  - acromion process of, 450
  - body of, 449
  - coracoid process of, 450
  - glenoid cavity of, 451
  - inferior angle of, 449
  - neck of, 450
- of septum of nose, 441
- skull, 715. *See* Skull
- spine, 859
- sternum, 446
  - compound, 446
- tarsal bones, 483
- tibia, 478
  - compound, 483
- toes, 483
- ulna, 457
  - coronoid process of, 458
  - union of, 459
  - olecranon process of, 457
  - union of, 457
- upper jaw, 442
- vertebrae, 859
- at wrist, 461
  - of zygoma, 442
- Fragilitas ossium (*Lat.* brittleness of bones), 500
- Freezing, anæsthesia by, 18
- Frequent micturition, 1083
- Frontal sinuses, abscess in, 795
  - polypi in, 795
- Frost-bite, 300
  - treatment of, 301
- Function modified by inflammation, 31
- Functional disease, 2
  - disorders of bladder, 1079
  - of breast, 906
  - rectum and anus, 1017
- Fungus (*Lat.* a mushroom) of brain, 722
  - of dura mater, 731
  - granulations in ear, 777
  - hæmatodes (*aiua*, blood), 110
  - of skull, 731
- Funicular portion of peritoneum, 918, 942
- Furunculus, 304
- Fusible calculus, 1027
- Fusiform (*fusus*, a spindle; *forma*, shape) aneurism, 321
- GAIT affected by spinal concussion, 864
- Galactorrhœa (γάλα, milk; ῥέω, I flow), 906
- Galvanic wire cautery, 1011
- Galvano-puncture in aneurism, 340
  - in varicose veins, 406

Ganglion (*γαγγλίον*, a knot), 317

- chronic, 317
- compound, 317
- diagnosis from aneurism, 367
- in foot, 317
- hand, 317

Gangrene (*γάγγραινα*, from *γράω*, I corrode), 142

- acute, 142
- amputation in, 151, 275, 288, 337, 427, 520
- from aneurism, 145
- aneurismal varix, 146
- arrest of, 148
- from animal poisons, 144
- arrest of circulation, 144
- arterial obstruction, 145
- arteritis, 145
- causes of, 143
- from chemical decomposing agents, 144
- chronic, 143
- cold, 143
- from conditions of the part, 147
- of blood, 144
- contagious, 216
- in contused and lacerated wounds, 271
- dry, 143
- from electricity, 144
- embolism, 145
- external agents, 143
- extravasated blood, 143
- fever of, 148
- from fibrinous coagulum in artery, 145
- fibrinous obliteration of a venous trunk, 146
- in fracture, 425
- from frost-bite, 300
- hemorrhage, 143
- heat, 144
- hospital, 216
- hot, 142
- humid, 142
- idiopathic, 143
- incisions in, 270
- from inflammation, 57, 147
- treatment of, 78, 150
- injury, 143
- internal causes, 144
- of intestine in hernia, 917
- management of, 932
- after ligature, 337, 363
- of external iliac, 364
- femoral artery, 368
- subclavian artery, 360
- causes of, 337
- period after, 337
- treatment of, 337
- from, nerve-influence, deficient, 148
- line of demarcation in, 148
- of separation in, 148
- local signs of, 142
- after operations, 19
- for aneurism, 337
- after amputations, 689

Gangrene (*continued*)—

- after rhinoplastic operations, 793
- from phlebitis, 146
- phleboliths, 146
- pressure of aneurism, 322
- on vein, 145
- pulpy, 216
- from rigidity of coats of arteries, 145, 460
- rupture, partial, of artery, 145
- senile, 145, 401
- amputation in, 402
- duration of, 401
- treatment of, 401
- separation of sloughs in, 272
- sphacelus from, 143
- from strangulation, 996
- from tight bandaging, 146
- traumatic, 143
- amputation in, 275, 427, 520
- causes of, 143
- modes of occurrence of, 143
- spreading, 151, 272, 425, 519
- symptoms of, 272
- treatment of, 149. *See* Mortification
- from varicose aneurism, 146
- varieties of, 142
- from venous obstruction, 146
- wound of a main artery, 145
- Gangrenous inflammation, 59, 271. *See* Gangrene
- phagedæna, 216
- Gases, noxious, asphyxia from, 835
- Gastrotomy (*γαστήρ*, the stomach; *τέμνω*, I cut), 981
- Gelatinous cancer, 106
- polypus, 786
- General pathology and surgery, 20

# A GUIDE

TO THE

## EXAMINATIONS AT THE ROYAL COLLEGE OF SURGEONS OF ENGLAND,

FOR THE

### DIPLOMAS OF MEMBER AND FELLOW.\*

---

#### EXAMINATIONS FOR THE DIPLOMA OF MEMBER.

No one disputes the national importance of the Royal College of Surgeons, as the central home of biological science in this country—a science which represents the structure and functions of organized beings in health and disease, and the laws relating thereto. The possession of an absolutely unrivalled Museum of Anatomy—human, comparative, physiological, and pathological, though less complete—has long since rendered it simply impossible for any other institution to overtake the College in its vast material resources for *teaching* the science of life; and systematic expositions of these resources by Owen, Quekett, Huxley, and Flower, have, for a long period of years, attracted the profession in this and from foreign countries, with men of science in general, as students of Hunter's grand conception. Periodic orations have commemorated this epoch in the history of natural science. At the same time, the successive advancements and aspects of modern Surgery have been exhibited in yearly short courses of original lectures by some of the most distinguished Surgeons, past and present. But now, in the midst of reform and reorganization, relative to our medical corporate bodies, it seems desirable, and cannot be uninteresting, to inquire into what the College, as an *examining* board, has done meanwhile, and is doing, to sustain and extend the educational character of the profession, and to protect the just rights of the public in regard to the qualifications of men who are licensed to practise Surgery.

For this purpose I lately requested permission, which was readily granted by the President, to visit the College during the two examinations for the diploma of Member—the primary examination on Anatomy and Physiology, and the second or pass-examination on Surgical Anatomy and the Principles and Practice of Surgery. My visit had reference exclusively to the more important or *practical* part of these examinations. With the nature of the previous *written* examinations the profession is already familiar, the questions submitted to the candidates being duly published in *The Lancet* and other medical journals. But in order to present a

\* Enlarged from original communications to *The Lancet*, 1870, by the Author.

full and complete record of the examination for the diploma of Member, the written questions submitted to candidates in each of the two examinations on the occasions referred to are here introduced.

### PRIMARY EXAMINATION.

AT THE END OF SECOND WINTER SESSION.

ANATOMICAL AND PHYSIOLOGICAL EXAMINATIONS; 1870. April 23rd, from 1 to 4 o'clock P.M.—Candidates *must* answer four out of six questions. Answers to *less* than six questions will not be received before half-past 3 o'clock.

1. Describe the situation, attachments, and structure of the urinary bladder. Mention the portions of the bladder which are not covered by peritoneum, and the structures with which those portions are contiguous.
2. Describe the iris; its position, attachments, and structure. Mention its blood-vessels and nerves, and state the function it exercises in vision.
3. The thumb. Describe the position of the thumb, its bones, its articulations, its capability of motion, and the muscles by which its movements are effected.
4. Mention the muscles which enlarge the capacity of the chest during ordinary inspiration. Explain the mode by which ordinary expiration is effected.
5. Describe the changes which take place in the circulation of the blood after the birth of the child.
6. Describe the position and attachments (origin and insertion) of the biceps flexor cubiti, the brachialis anticus, the supinator radii, longus and brevis, the pronator radii teres, and the pronator quadratus. Mention the precise action of each muscle, and the nerve by which each is supplied.

The practical examinations on Anatomy and Surgery, which are most conclusive as the test of professional qualification, have not hitherto been made known. These examinations, which were instituted at the College in November, 1858, have been gradually developed during the last twelve years; and a recent report of the Court of Examiners, adopted by the Council in January of the present year, leaves no doubt of their general design. It is to test the student's practical knowledge of Anatomy and Surgery as the result of personal instruction.

PRACTICAL EXAMINATION ON ANATOMY; April 26th.—In the room, or theatre converted into a room, where the examination was held, several tables were arranged, on which were distributed a series of recent dissections and anatomical preparations of dissection, under flat glass receptacles, showing the regional and visceral anatomy of the body. The latter department of anatomy was supplemented by ordinary museum preparations arranged around the room. Textural anatomy, and the minute structure of organs, were provided for by four microscopes, and a useful series of microscopic preparations. At each table two examiners were engaged with a student or candidate for diploma. The general features of this anatomical examination may be here noted. Its essentially *objective* character was at once apparent. Accordingly, the *questions* asked were principally in the form of "What's this?" the examiner pointing at the same time to the object of his query. It will be evident that by this mode of examination a wide range of matter can be gone over in a limited time, as well as thus eliciting the student's knowledge of anatomical objects and facts.

Occasionally only, the student was asked to *describe* an object before

him; for that would imply the power of describing, and a facility of descriptive language, neither of which might be readily at command under the trying circumstances of an examination.

An enumeration of the following series of dissections and preparations will suffice to indicate the principal objects by which the student's practical knowledge of anatomy was tested.

*Regional Anatomy.*—Triangles of the neck, showing principally the relation and distribution of the blood-vessels; parotid region and side of the cheek, showing the course and opening of Stenson's duct; occipital region, showing the deep muscles, recti and obliqui; anatomy of the axilla; bend of the elbow; palm of the hand; Scarpa's triangle, showing the relation and distribution of the femoral vessels and anterior crural nerve; popliteal region, showing its boundaries, and the relation and course of the popliteal vessels and nerves; sole of the foot.—*Ligaments*: Temporo-maxillary articulation, ligaments, and inter-articular cartilage (a section view). Articulations and ligaments of the first two cervical vertebræ, one with the other, and as connected with the occipital bone; articulations and ligaments of the clavicle; shoulder-joint; elbow-joint; ligaments of the wrist and hand; hip-joint; knee-joint, showing the relative position of the crucial ligaments; head of the tibia, with the semilunar cartilages, showing their relative shape and size, as determining whether they formed part of the right or left knee-joint; ligaments of the ankle-joint, and of the foot.—*Bones*: Separate, and articulated in the skeleton. It will be in the recollection of those members of the College who underwent the examination some years since, that osteology then formed the only test of the student's objective knowledge of anatomy.

*Visceral Anatomy.*—Dissections and preparations of the brain. Lungs and heart, with their vessels in relative position, as seen when the anterior wall of the thorax is removed. Heart: section view, showing the course of the blood through its cavities. Stomach and liver: longitudinal section of the former organ when distended, showing its curvatures and fundus, orifices (cardiac and pyloric), and commencement of the duodenum; longitudinal section of the gall-bladder. Liver: showing its ligaments, lobes, and fissures; portal vein, hepatic duct, and hepatic artery, with their relative position at the transverse fissure. Intestinal canal; longitudinal section of the jejunum, presenting its valvulæ conniventes. Kidney, injected: longitudinal section, showing the relative position of the renal vessels and ureter at the hilus; also, the relative appearance and thickness of the pyramidal and cortical portions. Bladder, and urethra with penis, opened anteriorly; showing openings of the ureters, neck of the bladder, prostatic sinus, veru-montanum and sinus pocularis, with the openings of the common ejaculatory ducts; remainder of urethra, and trabecular structure of corpora cavernosa. Perineum, its ischio-rectal fossæ, and their boundaries, &c.

*Developmental Anatomy.*—Ossification of the bones; fœtal circulation, &c.

*Histology.*—As already stated, a series of specimens under the microscope were occasionally referred to, in order to test the student's objective knowledge of histology. For example, under one of the microscopes I observed a section of a tooth showing the dentine. Having regard to the great importance of textural anatomy, and of the minute structure of organs in relation to pathology, this portion of the practical examination on anatomy might be advantageously extended.

## SECOND OR PASS EXAMINATION.

AT THE END OF FOURTH YEAR.

EXAMINATION ON SURGICAL ANATOMY, AND THE PRINCIPLES AND PRACTICE OF SURGERY; April 29th, from 1 to 4 o'clock, P.M.—Candidates *must* answer at least four out of six questions. Answers to *less* than six questions will not be received before half-past 3 o'clock.

1. Describe the usual form of cancer affecting the testicle. Mention other structures which become affected during the progress of the disease. State the treatment which may be employed, and the probable result. 2. Mention the circumstances attending a compound dislocation at the ankle-joint which would induce you to amputate. 3. Describe the relative position of the subclavian artery in the third part of its course; and the different steps of the operation by which the vessel may be exposed. 4. Mention the kind of accident which might produce fracture of the base of the skull; and describe the symptoms which indicate such an injury. State the treatment to be adopted, and the probable or possible result. 5. Describe all the symptoms which indicate a fracture of the clavicle in the middle of the bone. State the position of the broken ends of the bone, and the cause of the deformity produced. Describe the treatment. 6. Myeloid tumour. Describe the local appearance and the symptoms of this tumour. Mention its microscopic character. State the treatment, and the probable result.

PRACTICAL EXAMINATION IN SURGERY, AND USE OF SURGICAL INSTRUMENTS AND APPARATUS; May 3rd.—On entering the room I saw four tables, on each of which lay a man stripped for the purpose of surgical examination. In the centre another table presented an assortment of surgical instruments, and ranged round the room in compartments, were bandages, splints, trusses, and other surgical apparatus indicated by placards—*e.g.*, made bandages, splints for arm, thigh, &c. The nude recumbent *figures*, for such they were, being perfectly motionless and passive, were well-formed and well-developed men; but they presented very different degrees of muscular development and contour, selected apparently for different objects of surgical examination. Thus, one man was of spare muscular development, but in his body the various bony prominences in the upper and lower extremities, stood out conspicuously. He was an excellent subject for *topographical* anatomy, as one of the examiners aptly designated it. Another man, of ample muscular form, was more suitable for amputation and the application of splints. A well-knit negro, whose picked-out muscles seemed to invite the ligature of arteries, supplied the subject requisite for this purpose. Red chalk was provided, so that the student should mark the course of the arteries, or of other subjacent parts, and the relative position of internal organs.

The prevailing character of this examination on Surgery, like that on Anatomy, was eminently practical, and designed to elicit the student's personal knowledge. He was asked to *point out* this, or to *do that*; occasionally only to give his reasons for something he had stated. While one examiner puts the student through his exercises, another makes notes of the questions, with certain remarks, on another paper, of "*good*," "*moderate*," or "*bad*." This last record is made, we believe, but rarely

and very reluctantly, for a second or third repetition of such failure might be fatal to the hopes of the student. At the expiration of ten minutes, announced by a bell-stroke, the student leaves the table where he has been engaged, taking with him the question-paper of his examination to another table, where the examiner is enabled to see what questions have been asked, in order to avoid any repetition. After another ten minutes the student passes on to a third; and lastly, to a fourth table. According to the sum total of marks in his favour, the candidate passes; or if adverse, he has "failed to acquit himself," &c., as the official notification subsequently announces.

The following questions illustrate the nature of this practical pass-examination on Surgery:—

*Lower Extremity.*—In synovitis of the knee-joint, point out the situations where the swelling presents. What structures restrain or prevent the appearance of swelling in certain parts of the joint? Put your finger on the insertion of the ligamentum patellæ, and name the prominence of bone. Mark, with chalk, on the skin, the course of the anterior tibial nerve, from its commencement to the ankle-joint. Under what muscle does the external popliteal nerve pass, below the head of the fibula? Point out the most common situation of fracture of the tibia. Point out the situations of fracture in the fibula and internal malleolus; constituting Pott's fracture. Twist the foot in the direction it then assumes; and why is it so turned? Lay hold of the foot, and mark the line of incision as for Chopart's amputation. Between what bones of the tarsus do you disarticulate? Do the same as for Hey's amputation. Lay hold of the second toe, and feel for the joint in amputation at the metatarso-phalangeal articulation. Mark the line of incision. Mark the course of the superficial femoral artery. Where would you compress the common femoral with your finger, and compress the artery? Apply a tourniquet. For flap-amputation of the thigh, in its middle third, direct how the leg should be held. Take this spatula and show where you would enter the knife, how transfix the limb, and where bring out the point of the knife. Indicate the lines of the flaps. Prepare the bone for the saw. Apply the saw. What main artery will require ligature, and where would you find that vessel? For ligature of posterior tibial artery, laterally, under the gastrocnemius, mark the line of incision; what muscle will be divided, and where will the artery be found? Apply lateral splints to the leg, and bandage from the foot. Put your finger on the internal abdominal ring; also into the external abdominal ring. What point of bone can be felt in the latter ring? Describe the course of oblique inguinal hernia. Show how to reduce the hernia. Select a proper truss; apply it. Make the requisite measurements with a tape, so that an instrument-maker in London may forward to you in the country a proper fitting truss. Put your finger on the saphenous opening in the thigh. What bounds it externally? Show how to reduce a femoral hernia, indicating the directions in which compression should be made, successively. Apply a spica bandage, also a double spica bandage.

*Upper Extremity.*—Compress the brachial artery with your fingers. Mark, with chalk, the course of the artery from the armpit to the bend of the elbow. Name the superficial veins in the arm, pointing them out severally. Apply a bandage, as for bleeding at the bend of the elbow. Place the arm in the direction it assumes from dislocation of the humerus into the axilla, or forwards, or backwards. What is the position of the

arm in fracture of the clavicle? Point out the acromion. Reduce a dislocation of the forearm backwards, placing your knee in position for counter-extension.

*Neck.*—Place the head as for tracheotomy. Mark the incision. Where should the trachea be opened? What vessels are in the way or proximate? Put your finger on the seventh cervical vertebra, and how do you know it?

*Thorax.*—Point out the situation of puncture for paracentesis thoracis. Mark, with chalk, the arch of the aorta; also the outline of the heart, and the apex where it strikes the wall of the chest. Mark the incisions for amputation of the breast.

*Abdomen.*—Point out the situation of puncture for tapping the abdomen. Why is that spot selected? Mark the lineæ semilunares. Mark the course of the abdominal aorta, and its termination. Also of the external iliac arteries. What is the relative position of the iliac veins? Where would you puncture the bladder above the pubes? Where, per rectum?

*Instruments.*—Select the instrument for puncturing the bladder per rectum. The instruments for lithotomy. Apply a trephine to the skull, placing the centre-pin in position. When should the latter be withdrawn? Apply a ligature to an artery, represented by the end of a bougie. Plug the nares, anterior and posterior, in the skull. Name various instruments on the table, and describe their uses.

CLINICAL EXAMINATION.\*—This examination consists in the diagnosis of, and statement of the treatment appropriate for, injury or disease, as exhibited by patients, in the average course of surgical practice. It forms part of the Practical Examination in Surgery, and the use of Surgical Instruments and Apparatus. The cases were such as may be seen mostly in the out-patients' room of any general hospital, and would be almost certainly met with during the period of Dressership required by the regulations of the College. Thus, among the cases brought forward in the first two Clinicals, were: an unreduced dislocation of the elbow-joint, of some duration; bony ankylosis of the hip-joint, consequent on arthritis, in a middle-aged man; a suppurating inguinal bubo; a synovial cyst in the popliteal space; an indolent ulcer of the leg, with the marks above of recent subcutaneous ligature in three or four parts of the long saphena vein. Candidates were requested themselves to examine, and state verbally what they found in these cases. For example, the hip-joint case presented, some shortening and eversion of the leg, and immobility of the hip-joint, so that in raising the limb on the pelvis, the latter moved with it and showed a characteristic fold in the abdominal wall, above the groin. This condition was also attended with some obliquity of the pelvis, and lateral curvature of the spine in the lumbar region, towards the sound side. The man's general health was good, or certainly not reduced as by recent and acute disease of the joint. After such examination, the diagnosis was asked, and the treatment—by the mechanical support of a high-heeled shoe. The other cases were gone through in like manner.

In the other part of this practical examination—that relating to external or topographical Anatomy, and Surgical Appliances—the course of examination was as heretofore. It comprised such questions as the following. Compress the subclavian artery with your thumb, in the third part

\* Instituted at the College, April 18th, 1871.

of its course. Point out where you would tap the chest, which margin of the intercostal space you would avoid, and why? Select and apply a truss for right inguinal hernia. Make the requisite measurements for such a truss. What splints would be used for a broken leg—fracture of both bones. Apply M-Intyre's splint. Apply side splints. Apply Dupuytren's splint for fractured fibula. These questions included the bandaging of the limb to secure the splints. Amputation of the breast: Place the arm in position, mark with red chalk the incisions, show how you would raise the breast, and to what depth, and how to remove any diseased axillary glands. The treatment of hæmorrhage in the operation, and secondary. Wooden-knives—in the shape of large scalpels and amputating knives—were used for the various representations of surgical operations, in the ligature of arteries, excisions, and amputations.

One feature in these practical examinations seems specially worthy of notice; it is the freedom from any embarrassment or difficulty to the candidate—assuming him to be well-prepared. This agreeable circumstance is partly due to the *objective* character of the examination, whereby readiness of language and much descriptive power are not at all essential to success; and the composure of the student is aided by the calmness and considerate bearing of the examiners. In one case, a candidate who laboured under great impediment of speech, but who evidently possessed the requisite knowledge, was facilitated by answering in writing; just a word or two on a piece of paper with a pencil, being quite sufficient for the questions—what's this, and what's that?

**PATHOLOGY AND SURGERY.**—This concluding subject of the practical pass-examination is held in the Council-room and large library adjoining. It is oral or *viva voce*; and each candidate is subjected to examination at two tables for a period of ten minutes at each table, making twenty minutes' examination instead of half an hour, as, until quite recently, has been the period. Examples: What is this? an angular curvature of the spine. Point out the caries. What are its consequences? In hip-joint disease, recognise the alterations which the head of the femur and acetabulum have undergone. Specimens of tumours or morbid growths, &c. Pathology being so directly supplemental to Practical Surgery, this part of the College examination might be most advantageously extended. But the College Museum, having no regular source of supply for the enlargement of its pathological department, should be aided by contributions from the hospitals, where duplicate specimens of value for the purpose of testing the student's knowledge are constantly accumulating.

**EXAMINATION ON THE PRINCIPLES AND PRACTICE OF MEDICINE.**—Candidates presenting themselves for the final examination for the membership or fellowship will be examined in Medicine, unless claiming exemption under the published regulations of the College. But a candidate who has passed an examination in Medicine for the membership, will not be required to pass any further examination in Medicine for the fellowship.

These regulations cannot be too widely known, for they concern most candidates for the diploma of Member, and many candidates for that of Fellow. The examination is written.

The following questions may be taken as illustrating the nature of this examination.

April 30th; from 1.30 to 3 P.M.—1. Give a short account of scarlet fever, and its varieties; your treatment of particular cases of the disease, and the method you would adopt to prevent its propagation. 2. Enume-

rate some of the commoner forms of the cutaneous diseases of the scalp, and their treatment. 3. Mention the principal Pharmacopœial purgative agents; and give the composition and doses of each.

*Oral or vivâ voce Examination in Medicine.*—This examination is held immediately at the termination of the *vivâ voce* in Pathology and Surgery; the candidates who have undergone the *written* examination in Medicine enter the adjoining room, or small library, and are subjected to questions by the examiners in Medicine. Each candidate is submitted to this additional test for ten minutes, and a second ten minutes when the first period has not proved satisfactory.

*Results of the preceding examinations for the diploma of Member.*—Primary examination, 1870, April 26th, 27th, and 28th: Number of candidates 103; 11 of whom had been up once previously, and 5 of the 11 twice before; the present occasion being their third trial. 43 of the whole number referred to their anatomical studies for three months. All these were candidates for the first time.—Second or Pass-examination, May 3rd and 4th: Number of candidates, 40; only 1 having been up on a previous occasion. 9 were referred for six months. The one previously referred, passed.—Medicine: Number of candidates, 24; 10 of whom were referred for a period of not less than three months.

In conclusion, the following general remarks will, I trust, not be unacceptable. As regards the *written* examination, the general characteristics of a "good" paper may be gathered from some of the most satisfactory, and which I have had the opportunity of carefully perusing. Each element of any question was answered successively, and nothing foreign to the question introduced. Conciseness and brevity are not only good qualities in a paper, but they enable the well-informed student to answer all the six questions, and with due allotment of space to each; instead perhaps of his being compelled to restrict his answers to the modicum requirement of only four questions, and possibly with an inadequate consideration of even these. Disregard of conciseness might lead the student unwittingly to be beaten by time; and the mere length of a paper is no measure of its sufficiency.

Having watched the course of *practical* examination in Anatomy and Surgery, it seemed to my judgment that students failed to acquit themselves satisfactorily mostly in topographical or external anatomy, and in the use and application of surgical apparatus. The former deficiency would appear referable to neglect on the part of the students to handle and observe for themselves the configuration of the body in the living, or even in the dead subject. Most dissectors' manuals give directions for observing, and a descriptive examination of, the various prominences and depressions to be seen and felt on the surface of the body, *before* commencing the dissection of the part in hand. But the student, in his eagerness to get the skin off and begin dissection, overlooks this very important preliminary knowledge of anatomy, and its relation to that beneath the surface. It should, however, always be remembered that the Surgeon, in practice, approaches the body from its exterior, and that the topography of the surface guides to the interior. The "crammed" student soon betrays his ignorance, by looking up to the ceiling for recollection when asked questions which can only be answered by using his unused eyes to see and his hands to feel. In regard to surgical apparatus, the want of practical knowledge must be referred to inadequate instruction in the Hospitals.

## EXAMINATIONS FOR THE DIPLOMA OF FELLOW.

## FIRST EXAMINATION.

ANATOMY AND PHYSIOLOGY; 1870. May 20th, from 1 to 5 o'clock P.M.—Answers to *less* than four questions are not received.\*

1. Describe the entire lachrymal apparatus, its use, and the manner in which its functions are performed. 2. Describe the intrinsic muscles of the larynx; the position, relations, and functions of each, and their nerve supply. Describe particularly the distribution of the motor and sensitive filaments of the superior laryngeal nerve, and the probable origin of each set of filaments. 3. State the chemical composition of bone, and the relative proportion of organic and inorganic matter. Describe the arrangement of the osseous tissue in a long bone—say the tibia. State the sources whence the tibia is supplied with blood, and describe how the arteries permeate its structure. 4. What is the condition of the humerus at birth? Describe its mode of growth in length and thickness, the order in which the epiphyses ossify, and the age at which each epiphysis is united to the shaft. 5. Describe the secretory structure of the liver, and give the arrangement and mode of distribution of the different kinds of vessels, where they reach or leave the lobules. 6. Describe the method of making a side view of the contents of the male pelvis, and give a general description of the parts thereby exposed.

PRACTICAL EXAMINATION ON ANATOMY; May 25th.—This examination has the same *objective* character as that for the diploma of Member, its design being principally to elicit the candidate's personal knowledge of anatomical objects and facts. Hence the common form of question. "What's this or that muscle, artery, or nerve?" But, unlike the examination for the membership, the candidate, as a more advanced student, or as a member, is far more frequently required to *demonstrate* by pointing out and naming the structures presented to view, or perhaps to *describe* the parts seen in an anatomical preparation or a recent dissection. Sometimes, in explanation of statements made, *reasons* are asked. Of this threefold mode of testing the candidate's knowledge, the latter seemed to offer the chief difficulty. The time of examination for each candidate is ten minutes at four tables, severally; a total period of forty minutes.

The anatomical series comprised—(1) Regional dissection in the recent subject, and elaborately prepared parts in spirits under flat glass covers, which were removed as occasion required for examination. (2) Visceral preparations, some injected and displayed in like manner. (3) Developmental anatomy—*e.g.*, of the fœtus, ossification of the bones. (4) Histology, represented by an admirable and highly useful series of mounted specimens under the microscope, eight of which instruments were in use.

The nature of the anatomical objects submitted for examination, and of the questions proposed, may be gathered from the following summary:—

\* By a recent Regulation, 1871, only *four* questions are now put, but *all* must be answered.

Base of the skull, showing the foramina, nerves, and vessels transmitted, represented by coloured wax rods; point out and name the several structures thus indicated. What is this bone? The palate bone. The right or left, and why? Name its processes and foramina. Point out the situation of the spleno palatine ganglion. In the skull, point out the course of the palatine nerves, and of the Vidian nerve. Lateral section of orbit, showing eyeball, muscles, nerves; sphenoid and temporal bones continuous, showing portio dura, &c. Point out the lenticular ganglion; name its connexions with nerves; the nerves supplying the muscles of the eyeball. Select the bones of the internal ear, and describe their relative position and connexions. Describe the structure of the Eustachian tube. What are its functions? Describe the distribution of the auditory nerve. Parotid region: describe the relations of the parotid gland, superficial and deep, and show where the duct enters the mouth. Side view of the muscles of the face, and of the neck in the triangular spaces: point out and name the muscles seen. Another preparation showing also vessels and nerves: what is this or that part seen? Occipital region, showing recti and oblique muscles, nerves, and vessels: name the parts. Constrictors of the pharynx: describe their origin and junction in the pharynx. Vertical section of pharynx posteriorly; showing its openings anteriorly, laterally, and inferiorly: point out and name them. Section of nose and mouth: name the parts seen. Larynx, showing intrinsic muscles: name them. Anatomy of the axilla; the bend of the elbow; the forearm; the palm of the hand; severally subjected to examination. From a collection of small bones, pick out the bones of the carpus, name each of them; and place them in relative position. Anatomy of Scarpa's triangle in the thigh; of the popliteal space; the leg; the sole of the foot; severally subjected to examination. Is this a male or female sacrum, and why? What are the relative directions of the neck of the femur, in the male and in the female? What anatomical mark of distinction is there common to all dorsal vertebræ, and which exists in no other vertebræ? When the abdominal muscles suddenly contract, what action is there on the testes, and why?

Section of the head through the longitudinal sinus, enclosing the encephalon: point out and name the parts seen. Base of the brain: point out the (apparent) origins of the cranial nerves, naming them from before backwards. What parts are supplied by these nerves—*e.g.*, by the third and seventh? Specify the muscles supplied by the portio dura. Section of a portion of the vertebral canal, enclosing the cord and spinal nerves: what region does the portion belong to, and why? Lateral section of the thorax, enclosing heart and lungs, &c.: point out the origin, course, and distribution of the phrenic nerve, &c. Anterior view of thoracic organs, vessels, and nerves: name the parts seen. The diaphragm, showing its upper surface, and circumferential attachments: point out and name the apertures, and the structures passing through them, also the nerves. What shape does the diaphragm assume in inspiration and expiration, respectively? What causes air to enter the lungs? What is the pressure of the atmosphere on the square inch? Pyloric orifice of the stomach, opened duodenum, with gall-bladder, and pancreas: specify these structures, describe their relative position, and relations to surrounding parts. Section of kidney injected: point out the renal vessels, and ureter, as seen at the hilus, and their relative position; an opened calyx and its connexion with a papilla; the structure of the pyramidal and cortical portions.

What is the structure of a Malpighian body? Side view of the pelvis and intra-pelvic organs: describe the parts seen.

*Histology.*—A series of highly useful mounted specimens were submitted to examination under the microscope by each candidate. They comprised, principally, textural anatomy, and the minute structure of some important organs. Thus, I noticed white fibres of fibrous tissue; fat-cells; blood-corpuscles; muscular fibres, voluntary and involuntary; cartilage cells, and intercellular matrix; kidney injected, showing arrangement of the vessels, and structure of Malpighian bodies; choroid coat of the eye. A candidate having recognised any such specimen, would be asked questions of a physiological character pertaining thereto. For example: blood-corpuscles gave rise to questions as to their relative proportion in the blood; the salts of the blood, and their relative proportions; the kind and quantity of gases present; the difference between arterial and venous blood; the changes produced by respiration, and the source of carbonic acid in the blood. In like manner, the minute structure of the kidney led to questions respecting its function as an excreting organ.

By the regulation of January 11th, 1866, students may pass the first examination, or that on Anatomy and Physiology, for the fellowship, at the end of their third year—*i.e.*, between the first and second or pass-examinations for the membership; and this regulation is found to considerably facilitate the arrangements of those who desire to take the higher diploma of Fellow.

#### SECOND EXAMINATION.

**PATHOLOGY, THERAPEUTICS, AND SURGERY, May 26th, from 1 to 5 o'clock, P.M.**—Answers to *less than four* questions are not received.\*

1. Describe the process of reparation which nature adopts to unite fractured bone, divided tendon, muscle, nerve, skin, mucous and serous membranes. 2. Describe the different forms of gangrene which may be produced—first, by disease of arteries; secondly, by lesions of arteries; thirdly, by acute inflammation. State the treatment to be employed in each case, and your reason for its adoption. 3. Describe the treatment which your observation and experience would lead you to adopt for the relief and cure of permanent stricture of the urethra. 4. Mention the different forms of disease, including malignant affection, to which the knee-joint is liable, and which may possibly render amputation or excision necessary. Describe the pathological conditions and the symptoms, local and constitutional, which would induce you to save a diseased knee with the view of obtaining ankylosis. 5. State the symptoms of congenital syphilis, and mention the internal lesions which frequently coexist. Describe the treatment to be adopted. Prescriptions to be written in full. 6. Describe the local symptoms which precede and accompany the formation of phlegmonous suppuration; and state the chemical, physical, and microscopic characters of pus.

**CLINICAL EXAMINATION OF PATIENTS, May 27th.**—For the purpose of conducting this portion of the *practical* examinations, various hospitals are visited, by permission of the authorities, and suitable cases selected by the examiners, agreeably to the surgical staff. Four of the recognised hospitals supplied the requisite amount of clinical cases on the last occa-

\* By a recent Regulation, 1871, only *four* questions are now put, but *all* must be answered.

sion—namely, Guy's, St. Bartholomew's, the London, and Charing-cross hospitals. Two examiners attend each hospital. It will be obvious that this clinical examination must be somewhat restricted in its range, both as to the choice of cases of disease or injury which shall have a fairly marked typical character, and in patients who are able to undergo such examination, however judiciously it may be conducted. The examination is partly written and partly oral. Each candidate is required to examine a patient, and take notes in the form of a short clinical report of symptoms, or signs, and diagnosis. Of course, the bed cards, indicating the nature and treatment of the case, are removed. The time allowed is twenty minutes. The examiners then return and receive the report, folded up, and bearing the candidate's number. He is taken to a second case, one whereon another candidate had been engaged for his written report; he is first requested to examine that case, and then the oral questioning commences, ten minutes being the period. Thus, each candidate is submitted to clinical examination for half an hour. The relative merits of the written and oral modes of examination at the bedside, as a test of clinical knowledge, is a disputed question. But one eminent examiner, who has had experience of both modes, at the University of London and the College of Surgeons respectively, gave his decided opinion in favour of the oral method for eliciting the candidate's qualifications at the bedside.

The following cases and series of questions will illustrate the general nature of this oral examination. Of four cases selected at one hospital, two were well marked by their positive signs, the other two being valuable for examination principally in virtue of their negative signs as compared with other forms of disease or injury.

1. Disease of the hip-joint, without dislocation, in a boy. The student having examined this case, was asked—What is its nature? Point out the signs. What is the state of the joint? In what stage is the disease? How would the articular cartilage disappear? Might the acetabulum be affected? What kind of ankylosis will probably ensue? Why more probably fibrous? What dislocation does this disease of the hip-joint resemble? In morbus coxæ, does dislocation ever ensue? Are any of the viscera likely to be affected? What organs? What is the constitutional character of the patient? Why scrofulous? What is your prognosis in the present case? What treatment? If excision, mark the situation and length of the lines of incision. What vessels or nerves might be wounded in the transverse cut? 2. Sinus-openings, discharging just above the fold of the groin; the thigh is drawn up, but not inverted; the hip-joint is freely moveable, and without pain; the patient a man of middle age, with marked hectic. Is this disease of the hip-joint? You say it is—why so? If not—why not? 3. Injury of hip-joint, in a woman, aged sixty. There is some pain in the joint when moved, and inability to raise the limb from the bed; but there is no shortening nor eversion, and no crepitation can be felt in the joint, nor is there any discoloration about the hip or in the groin, although it should be remembered this might have disappeared, some time having elapsed since the accident. Is this a fracture of the neck of the femur? If not—why not? What treatment? If a fracture—how long would you keep the patient in bed at her age? 4. Secondary syphilis. Copper-coloured, scaly eruption, in a young woman. Name the eruption. What appearances are characteristic? What treatment?

OPERATIONS ON THE DEAD SUBJECT; May 28th.—In the college theatre, converted into a room, two adult subjects were provided, and instruments laid out on adjoining tables. Two examiners were engaged with each candidate. He is requested to perform a certain operation, aided by an assistant when necessary. The candidate is required to select the appropriate instruments, and to give instructions to his assistant—*e.g.*, as to the position of a limb for amputation, or the compression of a main artery. During the operation, or afterwards, questions are asked as to the parts seen or concerned; and lastly, as to the dressing of the wound. A second operation may then be undertaken. There is no specified period for the examination of each candidate.

The following operations may be taken as illustrative of the requirements in this portion of the practical examination:—They comprised amputations, excisions, and the ligature of arteries. Thus, I witnessed amputation of the fingers; at the wrist-joint; in the forearm; at the shoulder-joint; of the great toe, at the tarso-metatarsal articulation; Chopart's operation through the tarsus; and amputation below the knee. Excision of the knee-joint, and of the elbow-joint. Ligature of the sub-clavian artery, in the third portion; of the common carotid; and of the anterior tibial artery.

PATHOLOGY AND SURGERY; May 28th.—This concluding part of the practical examination takes place immediately after the operations, and it is held in the Council-room and large library adjoining. Four tables were placed, and two examiners at each, with osseous specimens, comprising diseased joints and bones, and spirit-preparations of other parts. The candidate passes a quarter of an hour at each of two tables, making half an hour's oral or *visà voce* examination—a longer period by ten minutes than in the corresponding examination for the membership.

The questions are principally and primarily objective; a specimen of diseased joint, for example, being handed to the candidate as the starting point for questions respecting its pathology and surgery. *Senior* candidates are not unfrequently asked, in the first instance, what *cases* they may have seen more particularly in their practice, as fractures or dislocations, and the object for examination is then selected accordingly.

The nature of this examination will be sufficiently exemplified by the following series of questions submitted to one of the candidates:—What is this osseous specimen? A fracture of the neck of the femur. Why so? Was the fracture extracapsular or intracapsular? Is it impacted? Was there any injury to the great trochanter? What age probably was the patient? Mention the signs of extracapsular fracture. Also those of impacted fracture. The treatment of these conditions. What is this? A fracture of the neck of the humerus. What would the signs be? The treatment? Compound dislocation of the elbow-joint, and its treatment. Chronic cystitis: what are its symptoms, and the condition of urine? What is the cause of its alkalinity? What are the elements of carbonate of ammonia? The treatment? Enlarged prostate: give the symptoms; the treatment for retention; the kind of catheter; how to teach the patient to use it. Glaucoma: what are its symptoms? The diagnosis of acute and chronic glaucoma; treatment, by what operation? Describe iridec-tomy. Describe the appearances in the human eye as shown by the ophthalmoscope, in health and disease. Describe Symp's operation at the

ankle-joint. Also Pirogoff's. What conditions are relatively favourable for one amputation rather than the other? Are there any objections to Pirogoff's operation? What is this osseous specimen? Rheumatic arthritis of the hip-joint. What are the characteristic appearances? What the signs? The treatment? What are the distinctive morbid appearances of scrofulous disease of the joint? At what age probably would it occur? What is this specimen? The scapula showing the glenoid cavity of an old dislocation. In amaurosis, what are the various ophthalmoscopic appearances? What are the various specific forms of iritis? The characteristic appearances of rheumatic iritis, and its treatment?

EXAMINATION ON THE PRINCIPLES AND PRACTICE OF MEDICINE; May 27th, from 1.30 to 3 P.M.—1. In what diseases may albumen and blood in the urine occur together, or separately? How do you treat the respective cases? 2. Describe the appearance of a lad who is the subject of well-marked inherited syphilis; also mention some of the complaints amenable to treatment to which he is liable. 3. Mention the various agents employed to produce anæsthesia by inhalation, and their mode of administration.

*Oral or vivâ-voce examination.*—This takes place immediately after the termination of the examination on Pathology and Surgery; the candidates passing on to the adjoining small library. Each candidate is submitted to various questions for a quarter of an hour, by the two examiners in Medicine; and a second quarter of an hour is added when necessary.

Both examinations in Medicine are compulsory, as for the diploma of Member, excepting under the conditions claiming exemption, according to the published regulations of the College. But a candidate who has passed an examination in Medicine for the membership, will not be required to undergo any further examination in Medicine for the fellowship.

*Results.*—On the occasion of the foregoing examinations for the diploma of Fellow, the following results may be interesting:—Primary examination: The number of candidates was 59, being the largest number yet known on any one occasion. 18 were members of more than eight years' standing and therefore were not required to produce certificates of professional examination, or of having passed the preliminary examination in general knowledge. 9 were members of less than eight years, or junior members. 19 had passed the primary or anatomical examination for the membership; the remainder had not passed any professional examination. This fact is significant, as showing that a large proportion of candidates come up at once for the fellowship without previous membership; and it is an increasing number. 10 of the whole number were referred to their studies for six months—*i.e.*, 49 passed. Of the 10, 1 was a senior member, 3 were juniors, 2 had passed the Anatomy for the membership; and 4 no professional examination. This result shows that the examination is made more rigorous to those who had undergone no previous professional examination.—Second or Pass-examination: 21 went in, being 17 out of the 59, and 4 who had passed the anatomical at a previous date. 14 were senior members, 6 junior, and 1 not a member, but who came up at once for the fellowship. 2 candidates, 1 senior and 1 junior, were referred for twelve months. This period is never made less excepting under very special circumstances, as the recall of an army surgeon to India.

In conclusion, I would venture to offer the following general remarks with regard to the fellowship examination:—

Respecting the *written* examination, the qualities of a “good” paper, whether anatomical or surgical, may be gathered from those which I have carefully perused. Each element of any question should be answered, and in successive order; but nothing foreign to the question introduced. Conciseness and brevity are valuable qualities, and especially as enabling the candidate to answer all the questions, and with due allotment of space to each, in the time allowed for examination. In the surgical paper by *senior* members, some reference to the candidate’s own experience of cases may not unreasonably be expected, just briefly stated by way of illustration. Some evidence also of more special reading than could perhaps be gathered from a general text-book on Surgery would indicate that higher and larger range of thought and aspiration which should distinguish a Fellow of the College. References, therefore, to standard authorities on Pathology and Surgery, and to their original observations, can scarcely fail to be acceptable.

In the *practical* examinations, operations on the dead subject are only an undressed rehearsal, as it were, of the representative procedures on the living body, as *surgical* operations. Due allowance therefore must be made for the different, and in some respects unfavourable, circumstances in which candidates are placed at the College. Moreover, the want of an adequate supply of subjects in the schools restricts the opportunities for practice even on the dead body. These, and perhaps other reasons, combine to render the operations at the College the least satisfactory part of the whole course of examination.

THE END.
